Attention: Dr. William Moorman
Project Officer

Gentlemen:

Contract No. 210-78-0037
Investigation of the Long Term Inhalation
Effects of Fibrous Glass
G-7188

Battelle is pleased to submit to you five (5) copies of the above report. All data included in this report have been checked by the BCL Quality Assurance Unit for consistency of data.

We feel the results of the study could be best disseminated by five papers dealing with toxicology, animal care, respiratory physiology, fiber preparation, and powder generation. Probably the most likely journals would be the Journal of Environmental Pathology and Toxicology, American Association of Laboratory Animal Science, Journal of Experimental Physiology, and Powder Technology.

Very truly yours,

Ralph I. Mitchell, Ph.D.
Project Manager

SUMMARY

The objective of this study was to determine the extent of potential toxicologic effects of fibrous glass particles during long-term inhalation exposure of Fisher 344 rats and Cynomolgus monkeys. The investigation, under a National Institute for Occupational Safety and Health (NIOSH) contract, was conducted at the Battelle Memorial Institute's Columbus Laboratories, Columbus, Ohio. This 18-month inhalation study was initiated on September 28, 1978, and exposures begun on March 12, 1979 with 100 rats (50 of each sex) and on June 19, 1979 with 12 male Cynomolgus monkeys for each of the 5 exposure levels.

Rats and monkeys were exposed to target concentrations of fibrous glass as follows:

Test Group	Fiber	Concentration (mg/m^3)
1	4 to 6 μm diameter; > 20 μm length with red binder	15
2	0.5 to 3.5 μm diameter; > 10 μm length with yellow binder	15
3	< 3.5 μm diameter; > 10 μm length	5
4	< 3.5 μm diameter; < 10 μm length	5
5 (Control)	None	0

The test atmospheres were generated by dispersing pre-sized fibrous glass in conditioned clean air for 7 hours per day, 5 days per week (excluding holidays) for 18 months (monkeys) and 21 months (rats) respectively. Control groups of animals were subjected to the same procedures as the test groups except that exposure was to clean air. During nonexposure periods, the control and test animals were housed in separate rooms. The exposures were terminated during the interval of 12-24-80 to 1-17-81.

Body weights, clinical signs of toxic effects, and mortality were followed throughout the study. Blood samples were taken for hematologic and clinical chemistry analyses twice before treatment and at weeks 16, 32, 48, and 64 during exposure (monkeys) and just prior to necropsy for rats and monkeys. Respiratory function was evaluated before exposure, after 9 months of exposure, and at sacrifice following 18 months of exposure (monkeys). Rats were held an additional 3 months, after their last exposure (age of 27 months), before they were sacrificed. A complete gross pathologic examination was conducted after sacrifice and a predetermined selection of tissues were taken.

After the 18 months of exposure, the mean fibrous glass concentrations in the chambers during exposure periods were calculated and compared with

the targeted concentrations given below:

Rats (21 months of fibrous glass exposure)

Group	Target (mg/m^3)	Measured (mg/m^3)
FO 1	15	13.96 ± 4.16
FO 2	15	14.94 ± 4.55
FO 3	5	4.85 ± 1.66
FO 4	5	4.78 ± 1.52
FO 5 (Control)	0	0.00 ± 0.00

Monkeys (18 months of fibrous glass exposure)

Group	Target (mg/m^3)	Measured (mg/m^3)
FO 1	15	14.72 ± 3.78
FO 2	15	15.62 ± 4.06
FO 3	5	5.04 ± 1.58
FO 4	5	4.78 ± 1.44
FO 5 (Control)	0	0.00 ± 0.00

Mortality

During the exposure period, 187 rats died spontaneously or were terminated in moribund condition. Two monkeys did not survive through the test period. One died early with a syndrome analagous to diabetes mellitus and the other was sacrificed in moribund condition. Neither death is considered to be the result of exposure.

Ophthalmologic Examinations

There were no postexposure lesions attributed to fibrous glass exposure.

Clinical Observations

None of the clinical signs recorded for monkeys or rats is considered to be the result of exposure to the fibrous glass test material.

Body Weights

There were no significant effects upon body weight from exposure of the rats or monkeys to any of the levels of fiber during the course of the experiment.

Hematology and Clinical Chemistry

In monkeys, there were no changes in group mean values that were outside the expected range nor were there biologically significant variations from control values that were associated with fiberous glass exposure. Also, in rats, there were no exposure related changes in hematology or serum chemistry values.

Pulmonary Function Evaluations

Pulmonary physiology measurements were performed in all monkeys in this study at 0 months, 9 months, and 18 months postexposure. Only a limited number of parameters were observed to deviate from control values during the study. The 9 and 18 month evaluations produced different patterns of respiratory response. Neither the 9 month nor the 18 month pattern was representative of restrictive or obstructive lung impairment. At the level of statistical significance chosen ($P < 0.05$), the changes could not be interpreted as lung debilitation.

Histopathology

Based on the histopathological investigation the following observations and conclusions summarize the findings of this study.

- The only unequivocal responses induced by fibrous glass inhalation in monkeys were macrophage aggregates with phagocytized fibrous glass in the lungs and tracheobronchial lymph nodes.
- The pulmonary responses in the rat induced by fibrous glass inhalation were characterized by macrophage aggregates and granulomas which contained fibrous glass fibers. The grossly visible plague like foci resulted from accumulations of granulomatous foci in pleural and subpleural locations. These lesions were limited to granulomatous foci, there was no fibrosis and there were no growth alterations in adjacent tissues, therefore there is no evidence in these animals that any further sequelae would result beyond that observed.
- There was no evidence of a fibrous glass induced fibrogenic response in either monkeys or rats.
- The most severe lesions in rats were in the F04 group (< 10 micrometers x 1 micrometer, no binder) whereas the response in the F01 group (>20 micrometers x 4 to 5 micrometers, with binder) was minimal.
- The severity of response in monkeys was similar for all exposed groups except the F01 group (>20 micrometers x 4 to 6 micrometers, with binder) in which the response was minimal. Group F01 also had monkeys which had mildly increased numbers of lymphoid nodules or aggregates in peribronchiolar and perivascular areas. The significance of the increase in the lymphoid aggregates is unknown but the most probable explanation would be a mild stimulation from an antigen such as the binder.
- The fibrous glass induced lesions were similarly distributed among all lobes of the lung in monkeys; in rats, the lesions were most prominent in posterior lobes in all but the F04 group where there was more equal distribution throughout the lung.

- The relative influence of fiber diameter, fiber length, concentration, and binder could not be evaluated due to variation of more than one factor in each animal group.
- The only evidence of translocation of fibers occurred in macrophage transport to draining pulmonary lymph nodes in many animals (rats and monkeys) and to mesenteric lymph nodes in two rats.
- The mononuclear cell leukemia was statistically significant when each test group was individually compared to the control group. The possibility of an exposure related incidence of this neoplasm cannot be ruled out.
- This study showed no evidence of pulmonary or mesothelial carcinogenicity associated with inhaled fibrous glass.

Data and Tissue Storage

Raw data, protocol, and a copy of the Final Report will be stored in the BCL Biological Sciences Department Archive. Tissue specimens, paraffin blocks, and slides will be transmitted to the Sponsor upon completion of the contract.

INTRODUCTION

The fibrous glass industry is a little less than 50 years old and within one generation has become one of the most versatile manufactured products, with a myriad of uses. In 1982, the annual production is between 3.5 to 4 billion pounds per year, with a value of approximately 2 billion dollars; however, because of its use for insulation and its ability to replace asbestos, the production rate should increase significantly. NIOSH estimates that 200,000 persons in the U.S. may be exposed occupationally to fibrous glass.[1]

To date, the major biological effects in human exposure to fibrous glass have been irritations to the skin and mucous membranes, as well as a very slight indication of an excess mortality risk due to nonmalignant respiratory diseases.[2] Although there has been concern that long term inhalation of fibers would produce a variety of pulmonary diseases, there has been little verification from most of the epidemiologic studies conducted so far. Most of the epidemiologic studies have been poorly designed and have failed to include the health outcomes of many workers who have been occupationally exposed for long periods of time.

A possible explanation for the fact that few health effects in humans have been found after fibrous glass exposure is that the nose is essentially 100 percent efficient in removing particles with aerodynamic diameters larger than 10 μm in diameter (depending upon the respiration rate) and can be completely efficient for particles as small as 6 μm. Essentially all of the fibers which are produced are greater than 4 μm in diameter and most of the fibers have a nominal diameter of 6 μm and the aerodynamic diameter of a fiber can be shown to be approximately 3 to 4 times the fiber diameter regardless of its length.[3] Thus, there is a low probability that such fibers can reach the lung during nasal breathing. This is verified by information obtained by Gross et al.[4] who showed that most of the fibers contained in the lungs of fibrous glass workers ranged between 1.5 and 2.5 μm in diameter and less than 6 percent of the fibers were greater than 4 μm. Consequently there is little reason to believe that typical worker exposure to the bulk of fibrous glass manufacture should produce an adverse pulmonary response.

However, micro fibers with diameters in the 1 μm size range should be of concern. Although these fibers only represent 1 to 2 percent of the total fibrous glass production, they are respirable and potentially carcinogenic. Animals that have been exposed to fibrous glass by various routes have shown fibrosis after intratracheal,[5,6] intrapleural,[7,8] and intraperitoneal[9,10,11] administration. Neoplasms have been observed after intrapleural and intraperitoneal administrations. Many of these studies demonstrated a relationship between fiber diameter and length and a specific biologic response.[12-14]

Although there have been several animal inhalation studies, they have produced inconsistent results. Some of the defects of these studies have been related to characteristics of the fibers, questionable mode of administration, insufficient exposure durations, lack of controls, etc.

Therefore, the National Institute for Occupational Safety and Health (NIOSH) initiated an 18-month inhalation study at Battelle Columbus Laboratories on September 28, 1978. The objectives of the study were to assess the adequacy of the current OSHA standard and to determine the character of pulmonary physiological and pathological responses produced by fibrous glass particles.

The study, which is reported herein, was initiated with 50 rats of each sex for each exposure concentration on March 12, 1979, and with 12 male Cynomolgus monkeys for each exposure level on June 19, 1979. Exposures to fiber glass were terminated during the interval 12-24-80 to 1-17-81. The monkeys were sacrificed immediately following the last exposure and the rats were held without exposure until they reached 27 months of age. The study was conducted and scheduled in accordance with the protocol in Appendix A. Deviations from the protocol are noted in the text. Appendix A also includes the standard operating procedures.

QUALITY ASSURANCE STATEMENT

This study was inspected by the Quality Assurance Unit and reports were submitted to management and the Principal Investigator as follows:

Phase	Date
Chamber Sampling	2/6/80
Pulmonary Function	4/23/80; 1/15/81
Blood Collection/Analysis	6/25/80; 11/3/80
Animal Body Weights	11/14/80
Animal Observations	11/14/80
Chamber Flushing	11/14/80
Ophthalmic Examinations	12/31/80
Animal Necropsy	12/23/80; 1/15/81
Data Audits	12/1/79; 4/28/81; 5/18/81; 6/5/81; 6/11/81; 6/12/81; 6/15/81; 6/18/81; 6/19/81; 11/11/81; 11/16/81; 12/3/81; 12/19/81; 12/28/81; 12/29/81
Report Audits	1/21/82; 4/30/82; 9/24/82
Reports to Principal Investigator and Management	Same as Data/Report Audits Above

To the best of my knowledge the methods described were the methods followed and the data presented accurately represent data generated during the study.

Ramona Mayer, Director
Quality Assurance Unit
Biological Sciences Department

MATERIALS AND METHODS

EXPERIMENTAL ANIMAL STUDY PROCEDURES

Experimental Animals

On October 24, 1978, Battelle received 64 male Cynomolgus monkeys, (all young adults) from Primate Imports, Long Island, N.Y. for use in this study. The monkeys were individually housed in stainless steel cages and were quarantined in rooms 7C-317 and 7C-318 of the Battelle Columbus Laboratories' animal facility. The monkeys were isolated in these rooms until three consecutive TB tests, three consecutive fecal flotations and three consecutive fecal cultures (for enteric pathogens) administered at 2 week intervals were all negative. Then they were released for study. During the week prior to the start of exposure, all monkeys' eyes were examined for possible lesions or abnormalities. Animals with eye defects would have been rejected before the randomization and group assignment procedure, but no lesions warranting such action were found.

On February 16, 1979, 275 male and 275 female Fischer 344 rats were received from Charles River Breeding Laboratories, Wilmington, Mass. to be used in the chronic fibrous glass study. The rats were 5 weeks of age when received. These animals were housed five per cage in conventional polycarbonate cages and quarantined in room 7C-316 of the Battelle Columbus Laboratories' animal facility. The rats were held in isolation in this room and were observed twice daily by a veterinary technician for 7 days after arrival and then released for study.

Group Assignments (Randomization)

The male and female rats were randomized separately by computer-generated group assignment. The monkeys were randomized in a similar fashion. The group composition was structured so that mean body weights were statistically similar across groups and so that there was no inter-group heterogeneity of variance.

The first step in the randomization process was to enter the individual body weight and identification number for each animal into the computer programmed to generate random numbers. The program presented a standard distribution of body weights for all animals in each category. In the case of rats, animals with weights at the extreme tails of the distribution (about 8 percent of the total) were eliminated before randomization. The animals were then assigned to groups so that congruent body weight distribution curves were assured. Rats were randomly assigned to individual cage compartments alternating female and male animals within each cage. Monkeys were kept in individual cages.

Housing

During the quarantine and set-up period before exposure, the rats were housed in polycarbonate cages containing bottle waterers. At the time of randomization, the rats were placed into stainless steel wire mesh cages for the duration of the study.

The cages, manufactured by Allentown Caging Company of Allentown, N.J., are 58 inches long, 12 inches wide, and 7 inches high. There are 12 compartments for animals and each compartment is 7 inches high, 5 inches wide, and 12 inches long. The cage and compartment dimensions are fully compatible with Institute of Laboratory Animal Resources/American Association for Accreditation of Laboratory Animal Care (ILAR/AAALAC) caging requirements. The two end compartments on either end are only 4 inches wide. Nine such cages were contained on one mobile stainless steel rack 60 inches long, 28 inches wide, and 70 inches high. Each rack was fitted with an automatic watering system manifold (manufactured by Hardco of Cincinnati, Ohio) located centrally on the rack. A quick-disconnect coupling was used to attach each rack watering system to the room supply. The stainless steel nipples protruded approximately 1 inch into each compartment when the cages were placed on their assigned rack. Beneath each pair of cages on a rack was a stainless steel pan to catch animal wastes. The racks were wheel mounted to facilitate transport of cages from holding rooms to the chamber room and back.

The monkeys were individually housed in stainless steel cages with automatic watering nipples that both fit into the exposure chambers and slid onto wall mounted racks between exposure periods.

During the study, animals in their respective cages and racks were housed in environmentally controlled animal holding rooms for approximately 18 hours per day. Of the 18 hours in the holding rooms, 12 hours were in darkness and 6 hours were in light. All test animals were housed separately from control animals. The rooms were identical in every respect. The animals were provided with a minimum of 15 fresh air changes per hour with conditioned air programmed for a temperature of 70° ± 2°F and a relative humidity of 45 ± 5 percent.

On an exposure day, racks were wheeled from holding rooms to the inhalation exposure room for loading into the exposure chambers according to a standard operating protocol. Exposure followed for a period of approximately 6 hours, including start up and shut down time. After exposure, the animal cages were loaded back onto transfer racks for the trip back to the animal holding rooms. During final loading, rat cages were relocated on the transfer racks daily according to a standard procedure in which a given cage was placed one position down on the rack. Thus, each cage systematically progressed through all possible positions within the exposure chambers.

Monkey cages were transported back and forth from the exposure chambers to the holding rooms via a wheeled cart. Monkey cages were returned to the same position in the holding room after each exposure but they were rotated within the chamber according to a similar plan.

All holding rooms and racks were washed down daily while the animals were in the exposure chambers and all cages and racks were changed and washed each weekend. Exposure chambers were washed daily after the exposure period ended and the animals removed.

Feed

The rats were fed Purina Rodent Chow 5001 (manufacturer's minimum content of 23 percent protein, 4.5 percent fat, and 6.0 maximum percent fiber). The feed blocks were placed in troughs fixed to the front of the compartments at the end of the daily exposure period. The feed troughs were left in place over the weekends.

The monkeys were fed Purina Monkey Chow 5038 (manufacturer's minimum content of 15 percent protein, 5 percent fat, and 5.0 maximum percent fiber). The biscuits were given to the monkeys in stainless steel cups at the end of the daily exposure period and in the morning and evening on weekends.

Monitoring Individual Animal Identification

During the pretest period, each rat was fitted with a numbered monel metal ear tag (manufactured by National Band and Tag Co., Newport, Kentucky). The tag number was the animal's individual identification for the duration of the study and duplicate sets of tags were purchased in case replacements were needed. At the time of randomization, master locator maps were constructed to record the placement of rats, one per compartment. Each animal was placed in a specific cage and compartment throughout the study. The monkeys were identified with an individual chest tatoo.

Clinical Observations

All animals (monkeys and rats) were observed twice daily throughout the pretest and study periods by experienced technicians.

During observation, each rat was designated as being normal (N) or abnormal (A) by a check mark in the appropriate box on the clinical observations form (see example in Appendix B). If the animal was designated as being abnormal, a free text description of the abnormality was recorded on the animal obervations form (see example in Appendix B).

For monkeys, the normal/abnormal designations for morning and evening observations and the free text descriptions of the abnormalities were all recorded on the Record of Daily Clinical Observations form (see example in Appendix B).

The observations were made between 6 and 9 AM before the animals were loaded into the chambers between 3 and 6 PM after the animals were removed from the chambers. On weekends, the observations were made before and after cage changing, feeding, weighing, and room cleaning.

Mortality was recorded on daily record sheets, in the Project Death Record Log, and in the computerized body weight data file.

Ophthalmoscopic Examinations

Pre-exposure and post-exposure eye examinations were performed on all monkeys in this study. Before examination, the pupils were dilated by instillation of a few drops of Mydriacyl (Alcon Laboratories, Fort Worth, Texas) into the eye of each animal (the monkeys were restrained for instillation and examination by trained animal handlers). Approximately 15 minutes later, the eyes were examined using a Welch-Allyn Direct Ophthalmoscope for fundoscopic examination and an American Optical Slit-Lamp Biomicroscope for examination of the iris, lens, cornea, and conjunctivae. A trained veterinarian, experienced in laboratory animal ophthalmology, conducted all ophthalmoscopic examinations.

Body Weight Determinations

The weights of all animals were recorded at the beginning of the study, weekly for the first month, and biweekly thereafter for the duration of the study. The rats were weighed individually using an automatic capture and recording system. The system consisted of Mettler PL 3000 digital balances, Hazeltine 1400 CRT terminals, Techtran cassette tape drives, paper printers, and programmable microprocessors. Data tapes containing the current animal census based on master locator maps generated by the master data base record were used to program the microprocessor.

Once the microprocessor was programmed, the technicians were given cage and compartment identification and the associated animal census. Weight data signals from the balance were collected on a cassette data tape (to be read later to the master data base) and were simultaneously printed on a paper copy. The paper copy was used to check the completed update of the data base.

Because weighing was done when the cages were changed on a week-end day, two teams of two technicians were required to weigh the animals, record their weights, and place all animals into clean cages. A strict standard operating procedure required the following:

(1) Positive cage identification by reading the metal plate in the first compartment for each cage.

(2) Positive animal identification on the rat in Compartment Number 1 (Cages 1 through 9).

(3) Recording the identification number of (2) above on the form.

(4) Weighing all animals (individual rats) in a systematic manner by weighing each compartment 1 through 12, left to right.

(5) Checking the animal census against the master locator maps.

Monkeys were individually weighed in their cages on a table balance. The cage weight was subtracted from the gross weight to give the animal weight and this number was recorded by the technician on weight data forms.

Hematology and Clinical Chemistry

Monkeys

Blood for hematologic and serum chemical analyses was collected twice before the initiation of exposures; at weeks 16, 32, 48, and 64 following exposure; and immediately prior to necropsy. The parameters that were evaluated at each interval included the following.

Hematology. Hematocrit, hamoglobin, RBC count, WBC count, reticulocyte count, platelet count, and differential count.

Serum Chemistry. BUN, glucose, creatinine, inorganic phosphorus, calcium, total bilirubin, cholesterol, LDH, SGOT, sodium, and potassium. Blood samples were obtained from the femoral vein following a fast of approximately 12 to 16 hours. Specific procedures used for the determination of each factor are described in Appendix C. Results are evaluated by qualitative examination of group means for baseline and terminal sampling periods.

Rats

Blood for hematology and serum chemistry analyses was collected just prior to termination. Blood was collected by cardiocentesis after anesthetization of the rats with pentobarbital sodium injected intraperitoneally. The parameters evaluated were the same as those described above for the monkeys. Ten rats per sex were selected randomly for these evaluations.

Results were evaluated by qualitative examination of group means and standard deviations of exposed rats as compared to the control group.

Pulmonary Function Evaluation

One aspect of determining the health effects of long term, low level inhalation exposure to fibrous glass is the assessment of the alteration of pulmonary performance in exposed individuals. The value of respiratory physiology measurements is that such evaluations, which are designed to assess the subtle impairment of respiratory function relative to occupational exposure and to monitor those changes with time, may be useful is predicting the disease course in man. Although some respiratory function debilitation may not be life threatening, it may be costly both in terms of human suffering and economic impact. It is, therefore, important to understand the nature and degree of functional alterations of the respiratory system. To that end, Battelle selected a battery of pulmonary function tests for this study.

The following pulmonary function tests were selected: dynamic lung resistance (R_L), dynamic lung compliance (C_L), inspiratory capacity (IC), functional residual capacity (FRC), expiratory reserve volume (ERV), carbon monoxide diffusing capacity (DLCO), closing volume (CV), anatomical dead space (VADS), phase III slope ($\%N_2$/100 ml), forced vital capacity (FVC), peak expiratory flow rate (PEFR), forced expiratory flow at 50%, 25%, and 10% of lung volume (FEF @n%), and forced expiratory volume at 0.5 (FEV5) and 1 second (FEV1). In addition, some parameters were normalized to lung volumes, when appropriate, to compensate for size differences and limiting effects of smaller volumes. Table 1 is a list of all of the pulmonary function parameters measured or calculated for this study.

Lung mechanics evaluations were determined using the techniques of Neergaard and Wirz[15] after direct recording of transpulmonary pressure, lung airflow rate, and respired gas volume onto an Electronics for Medicine VR-6 recorder. Dynamic lung volumes were obtained from recordings of lung volume plotted relative to airflow rate. Respiratory maneuvers necessary for these evaluations were induced by a positive-pressure plethysmograph by Charles Spanger and Associates. The design and operation of this device is described in detail by Moorman, Lewis, and Wagner.[16] A picture of this device is shown in Figure 1.

TABLE 1. PULMONARY ASSESSMENT PARAMETERS

R_L	Dynamic Airways Resistance	($CMH_2O/l/sec$)
C_L	Dynamic Lung Compliance	(ml/CMH_2O)
FVC	Forced Vital Capacity	(ml)
FEV.5/FVC	Forced Expiratory Volume in 0.5 seconds normalized to FVC	(%)
FEV1/FVC	Forced Expiratory Volume in 1 second normalized to FVC	(%)
PEFR	Peak Expiratory Flow Rate	(ml/sec)
FEF @n%	Forced Expiratory Flow at n% of lung volume	(ml/sec)
FEF @n%/FVC	Normalized FEF @n%	(FVC/sec)
IC	Inspiratory Capacity	(ml)
FRC	Functional Residual Capacity	(ml)
ERV	Expiratory Reserve Volume	(ml)
RV	Residual Volume	(ml)
TLC	Total Lung Capacity	(ml)
RV/TLC	Ratio of RV to TLC	(%)
DLCO	Diffusing Capacity of Carbon Monoxide	(ml STPD/min/mmHg)
CV	Closing Volume Ratio to Vital Capacity	(%)
CV+RV/TLC	Sum of CV and RV normalized to TLC	(%)
VADS	Anatomical Dead Space	(ml)
$\%N_2$/100 ml	Slope of Phase III N_2 Washout	(%)
Viso	Volume of Helium Isoflow	(ml)
Viso/FVC	Viso normalized to FVC	(%)

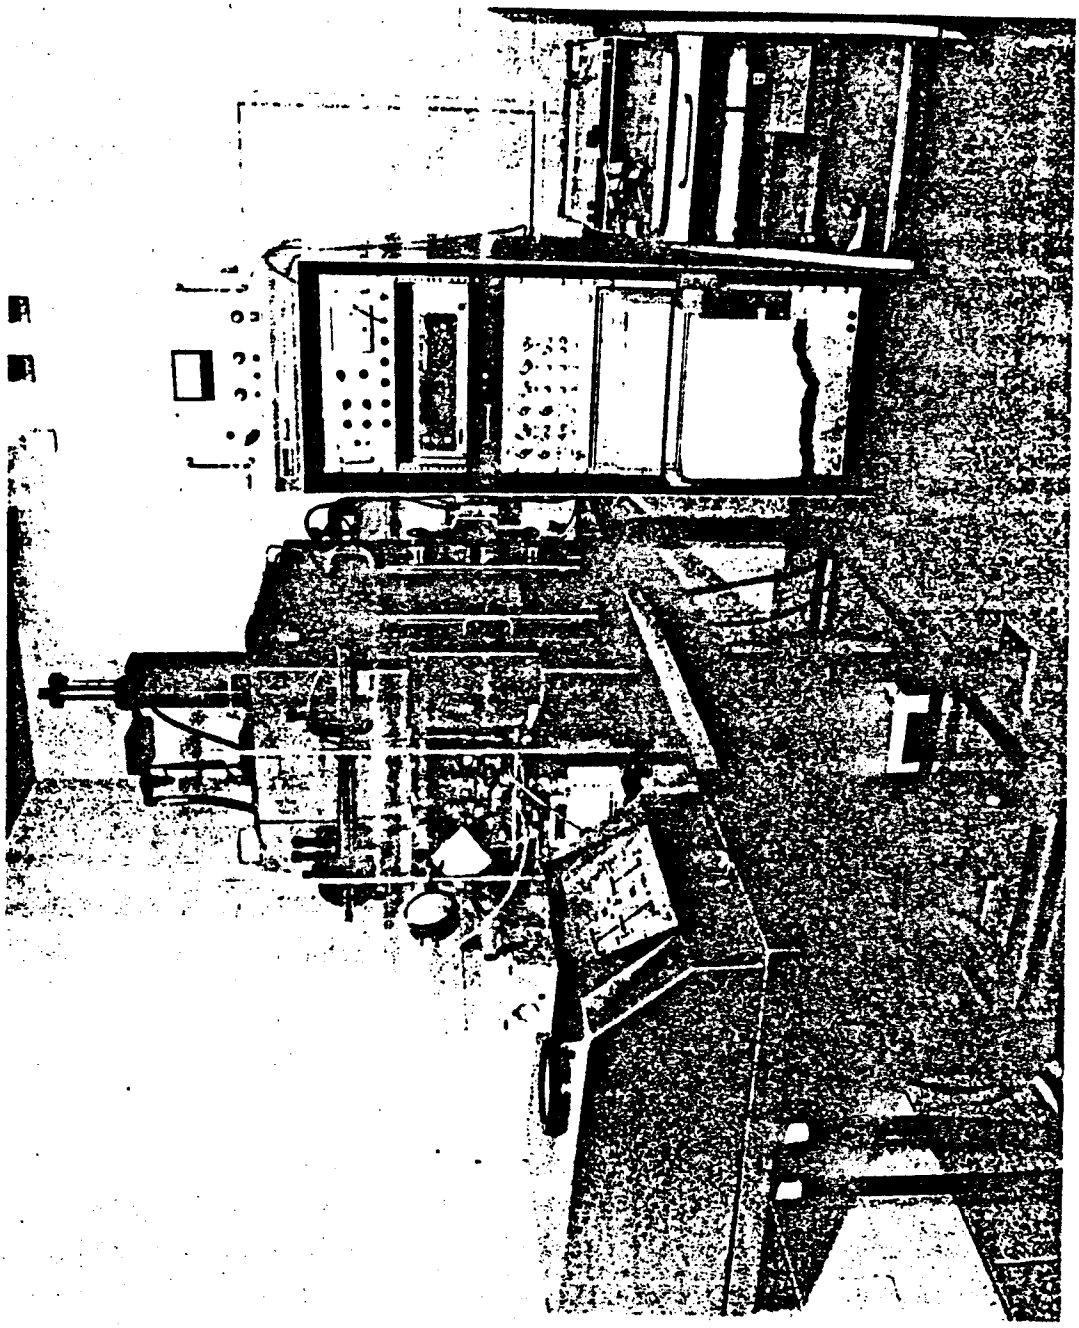

FIGURE 1. POSITIVE-PRESSURE PLETHYSMOGRAPH

The dynamic response characteristics of transducer systems used to evaluate pulmonary function information must exceed the frequency components inherent in the measured signals. Quiet breathing and forced expiratory maneuvers studied during this program do not typically exceed 4 Hz. No amplitude distortion or phase shift was observed in signals normalized to a simple harmonic motion device which provided reference flows up to 7 Hz. The plethysmograph compression time measured from -70 cm H_2O to +70 cm H_2O was determined to be 172 msecs $\pm$ 14 msecs with an n=10 trial. Transit time was measured by signals generated by electromechanical position switches used to control diaphragm excursion.

The volume of helium isoflow, the diffusing capacity of the lung for carbon monoxide, and the multiple breath N_2 washout test were executed as outlined by Hutcheon et al.[17], Ogilvie et al.[18], and Lewis et al.[19], respectively.

The 60 adult Cynomolgus monkeys were divided into 5 groups of 12 monkeys each for exposure and evaluation during this program. The generation and exposure conditions are discussed elsewhere in this report. Pulmonary function evaluations were performed at three time periods during the course of this study: once before the initiation of exposure, once after 9 months of exposure, and once after 18 months of exposure. Anesthesia was induced approximately 15 minutes before the beginning of the respiratory physiology measurements by the sequential introduction of ketamine (35 mg/kg) and Xylazine (5 mg/kg). Additional anesthetic was used, if necessary, to maintian adequate depth of anesthesia during the period of evaluation. The duration of evaluation was typically 30 minutes in length. The anesthesia regimen was selected because of its ease of introduction and its degree of safety.

Once the desired plane of anesthesia had been reached, the test subject was intubated with a shortened 20 FR Magill endotracheal tube and placed, sitting upright, in the plethysmograph. In addition, an esophageal balloon was placed in the lower third of the esophagus and the balloon was maneuvered to demonstrate maximum pressure fluctuations with minimal cardiac artifacts. The airflow through the endotracheal tube was monitored by a Hans Rudolph pneumotachograph and Validyne MP-45 pressure transducer. The esophageal pressures were also determined by a calibrated Validyne pressure transducer. The signals from these transducers, as well as the flow integrator and Med-Sciences

Nitrogen Analyzer, were recorded as necessary on an Electronics for Medicine VR-6 recorder. These recordings were subsequently evaluated to determine the respiratory performance of the test subject. After evaluations were completed, the subjects were returned to their cages to recover. Most monkeys appeared fully recovered after about 2 hours.

Gross and Microscopic Pathology

Monkeys

Detailed gross examinations were conducted on all monkeys and pertinent observations were recorded. Monkeys were terminated by anesthetization with pentobarbitol sodium, followed by exsanguination. The following tissues were removed and fixed in 10 percent neutral formalin.

Larynx	Urinary bladder
Trachea	Testes
Lung (section from each lobe)	Prostate gland
Heart	Ovaries
Liver	Uterus
Esophagus	Spleen
Stomach	Pancreas
Ileum	Kidneys
Colon	Adrenal glands
Pleural membrane	Pituitary gland
Nasal passages	Brain
Paranasal sinus	Thyroid gland
Tracheobronchial lymph node	Lesions or masses
Mesenteric lymph node	*Eyes

The tissues listed above were processed in the routine manner, embedded in paraffin, cut at 5 μm, stained with hematoxylin and eosin, and examined microscopically. Histochemical stains were utilized on specific tissues at the discretion of the pathologist to aid in interpretation of changes.

*Fixed in 3 percent buffered glutaraldehyde.

Rats

Detailed gross examinations were conducted on all rats and pertinent observations were recorded. Rats were terminated by intraperitoneal injections of pentobarbital sodium followed by exsanguination (if blood was collected for hematology and serum chemistry) or by CO_2 inhalation followed by exsanguination (if blood was not used for clinical laboratory procedures). Tissues removed for fixation and subsequent histologic examination were the same as those listed above for monkeys.

Statistical Analysis

Body Weights

The statistical analyses consist of body weight and weight gain analyses across dose groups at 0, 9, and 18 months for monkeys, and at 0, 9, and 21 months each for male and female rats. Percent weight changes over the entire measurement period, over the first 9 months, and over the remaining months were also analyzed across dose groups for monkeys and for each sex in rats. A survival analysis for rats only was performed, as only two deaths occurred among the sixty monkeys. These two early deaths were excluded from monkey body weight analyses as outliers because their weights were much lower than the other monkeys.

For each time period, the assumptions underlying a one-way analysis of variance were tested. Histograms and normal probability plots were used to determine the appropriate statistical test and to assess the normality within each dose group. Homogeneity of variance was tested by the method of Levene[20].

If the Levene statistic was not significant ($p > .05$), a one-way analysis of variance (ANOVA) was performed. If the ANOVA was significant ($p < .05$), a Dunnett's test[21] was used to compare each treatment with the control group. If the Levene statistic was significant ($p < .05$), a weighted ANOVA according to Welch[22] was performed. A t-test with Bonferroni's correction, assuming unequal variances was performed to compare treatment means with the control if the Welch test was significant. Because of outliers in the data for rats, a Kruskal-Wallis[23] nonparametric ANOVA followed by Dunn's[24] multiple comparisons was sometimes considered a more appropriate test. Such cases are noted and explained in the text.

Survival Analysis

Mortality data for rats was analyzed by the actuarial life table

method developed by Berkson and Gage[25]. For each group, survival information was printed and a nonparametric test devised by Desu[26] was used to compare groups.

All analyses were performed on Battelle's CDC 5600 and Cyber 74 computer systems using packaged programs[27-29]. For all analyses, the level of significance was $\alpha = .05$.

Chamber Concentrations

For each day and chamber, concentration levels were measured at various times throughout the day. Based on the measured reading obtained each time, the concentration level in the chamber was then manually adjusted toward a target level for the chamber. The data collected for each day and chamber included the measured concentration levels and the time period covered by each reading.

Statistical measures were computed to globally describe the concentration levels present in the chamber for each day. These measures included a time-weighted average of the concentration levels, a weighted measure of the variability in concentration levels, and the minimum and maximum levels. The assumptions upon which these descriptive statistics were based on as follows:

(1) There were two sources of variation for the concentration levels throughout the day:

- Variation due to manual adjustments of the levels.
- Random variation over time between each manual adjustment.

(2) The random variation was small relative to the variation due to manual adjustments. That is, a steady state condition existed between adjustments.

The formula used to compute the time-weighted average of the concentration levels is given by

$$\bar{X} = 1/T \sum_{i=1}^{N} T_i C_i \quad , \qquad (1)$$

where T_i is the length of time covered by the i^{th} measured concentration level, C_i, $T = \sum_{i=1}^{N} T_i$ is the total length of time the animals were subjected to fiber glass during the day, and N is the number of readings taken in the chamber on the given day.

The variability of the concentration levels throughout the day was estimated by

$$S^2 = 1/T \sum_{i=1}^{N} T_i (C_i - \bar{X})^2 \quad , \qquad (2)$$

where $\bar{X}$ and T are given in (1). Note that the formula given by (2) slightly underestimated the total variability in concentration levels since it does not include a component for the random variation over time between each manual adjustments. However, from Assumption 2, this component would be relatively small. The results for each day and chamber are given in Appendix D.

Finally, an average concentration level for each chamber over each quarter was computed by averaging the values for each day in the quarter. In addition, the lengths of test time for all the days were summed to get a total value for each quarter. The results for each quarter are given in Table 23.

Pulmonary Function

The one way analysis of variance (ANOVA) and the Kruskal-Wallis one way rank analysis of variance were used to evaluate the group statistics for the pulmonary data. Bartlett's test was used to validate the ANOVA. Those parameters that demonstrated non-homogeneous variance (Bartlett's $P > 0.05$) were tested by the non-parametric Kruskal-Wallis evaluation. For all procedures, the 95% level of significance was used.

FIBER PREPARATION AND GENERATION

FIBER PREPARATION

Four glass fiber fractions were required for the animal exposure program with general specifications of (1) 4 to 6 micrometer diameter fiber > 20 micrometers long, (2) 0.5 to 3.5 micrometer diameter fiber > 10 micrometers long, (3) < 3.5 micrometer diameter fiber > 10 micrometers long, and (4) < 3.5 micrometer diameter fiber < 10 micrometers long. Appropriate commercial production glass fibers were selected; and techniques were developed for grinding and classifying the fibers into fractions to meet these specifications.

During the 18 month animal exposure program, the four fiber fractions were produced on a lot basis and delivered daily for use in the exposure chambers. Each lot was examined and characterized to confirm that the fibers met the specifications for the exposure program.

Material Selection

Commercial grade glass fibers used in filters and insulation products were selected for making the required fiber fractions. The initial selection criteria were quantity production and fiber diameter in the required size ranges. Binders (formaldehyde based resins) were required on fibers in two of the fractions.

Four commercial products were selected for evaluation as follows:

(1) FG Insulation Fiberglas*, 4 to 12 micrometer diameter fiber with 4.5 percent binder (red - urea and phenol formaldehyde)

(2) FM Series Air Filter Media*, 1 micrometer diameter fiber with 12.5 percent binder (yellow - phenol formaldehyde)

(3) FM Series Air Filter Media*, 1 micrometer diameter fiber without binder

(4) Tempstran Code 100/475**, 1 micrometer diameter fiber without binder.

---

* Owens-Corning Fiberglas Corporation, Newark, Ohio 43657

** Manville Corporation, Denver, Colorado 80217

Based on grinding and classification tests, the red FG Insulation Fiberglas and yellow FM Series Air Filter Media were selected for making the two fiber fractions with binders, and the Tempstran Code 100/475 glass fiber was selected for the two fractions with < 3.5 micrometer fibers > 10 micrometers and < 10 micrometers long.

Size Reduction

To meet the length requirements of the four fiber fractions, various grinding methods were investigated to break up the commercial glass fibers without destroying fiber integrity. Appropriate methods were selected to produce the fibers in the relatively large quantities needed in the inhalation program.

Several grinding mills (see below) were evaluated for (1) fiber production rate, (2) retention of fiber integrity with minimum overgrind, and (3) minimum contamination.

Name of Mill	Type of Mill	Manufacturer
Mikro Atomizer	High Speed Mechanical Pulverizer	Pulverizing Machinery Co., Summit, N.J.
Ball Mill	Ball Cascade	---
Glen Creston Mill	Hammer Mill	Glen Creston Ltd., Middlesex, Eng.
Fitz Mill	Hammer Mill	The W.J. Fitpatrick Co., Chicago, Ill.
Waring Blendor (Century 8)	Sluar	Dynamic Corp. of America, New Hartford, Conn.
Gem-T Mill	Fluid Energy	Geo. W. Helme Co., Inc. Helmetta, N.J.
Rod Mill	Rod Cascade	Denver Equip. Co., Denver, Col.
Willy Bleuler Apparatebau	High Energy Ring Mill	Zollikon-Schweiz, Switzerland
Planetary Mill	High Energy Ball Mill	Steel and Cowlishaw Ltd., Hanley, Stoke-on-Trent, England

Test grinds from each of the grinders yielded different results. The Waring Blendor and Gem-T fluid energy mill separated the fiber bundles but did little grinding on the 4 to 12 micrometer diameter Insulation FG

Fiberglas. The hammer mills such as the Fitzmill, Glen Creston mill, and the high speed Mikro Atomizer generally produced fiber lengths of 100 to 400 micrometers in the large diameter fibers. However, the hammer mills and high speed mechanical pulverizer were not effective in grinding the 1 micrometer diameter fibers. The fibers apparently charged electrically and collected in the housing and on the hammers.

Ball milling and grinding with the Willy Bleuler Apparatebau grinder were the most effective techniques for producing short fibers from the commercial glass fibers.

Ball Mill

Ball milling in 1.5 ℓ ceramic jars reduced the length of the 1 micrometer fibers but overground the 4 to 12 micrometer fibers when the ball jars were loaded with 1.2 kg of 0.5 cm ceramic balls and 3 grams of fiber. The 4 to 12 micrometer diameter fibers were reduced in diameter as well as in length. The best results were achieved by dry grinding with a rotational speed of about 75 rpm. The 1 micrometer diameter fibers without binder generally ground to 95 percent < 5 micrometers in 4 to 6 hours. This material was satisfactory for making the < 10 micron fractions. A shorter grind of 30 to 45 minutes produced fibers that were predominately (90 percent) in the range of 10 to 30 micrometers, satisfactory for making the > 10 micrometer fractions.

Wet grinding with 300 ml of water per load reduced the grinding rate. Only about 75 percent of 1 micrometer fiber with binder was in the range of 1 to 10 micrometers long after 30 hours of grinding. By comparison, 24 hours of dry grinding of the same fiber yielded about 90 percent that were less than 10 microns.

Fiber fractions produced by dry grinding of the 1 micrometer Tempstran fiber for periods of 0.75, 2, and 4 hours are shown at 500X magnification in Figures 2, 3, and 4 respectively.

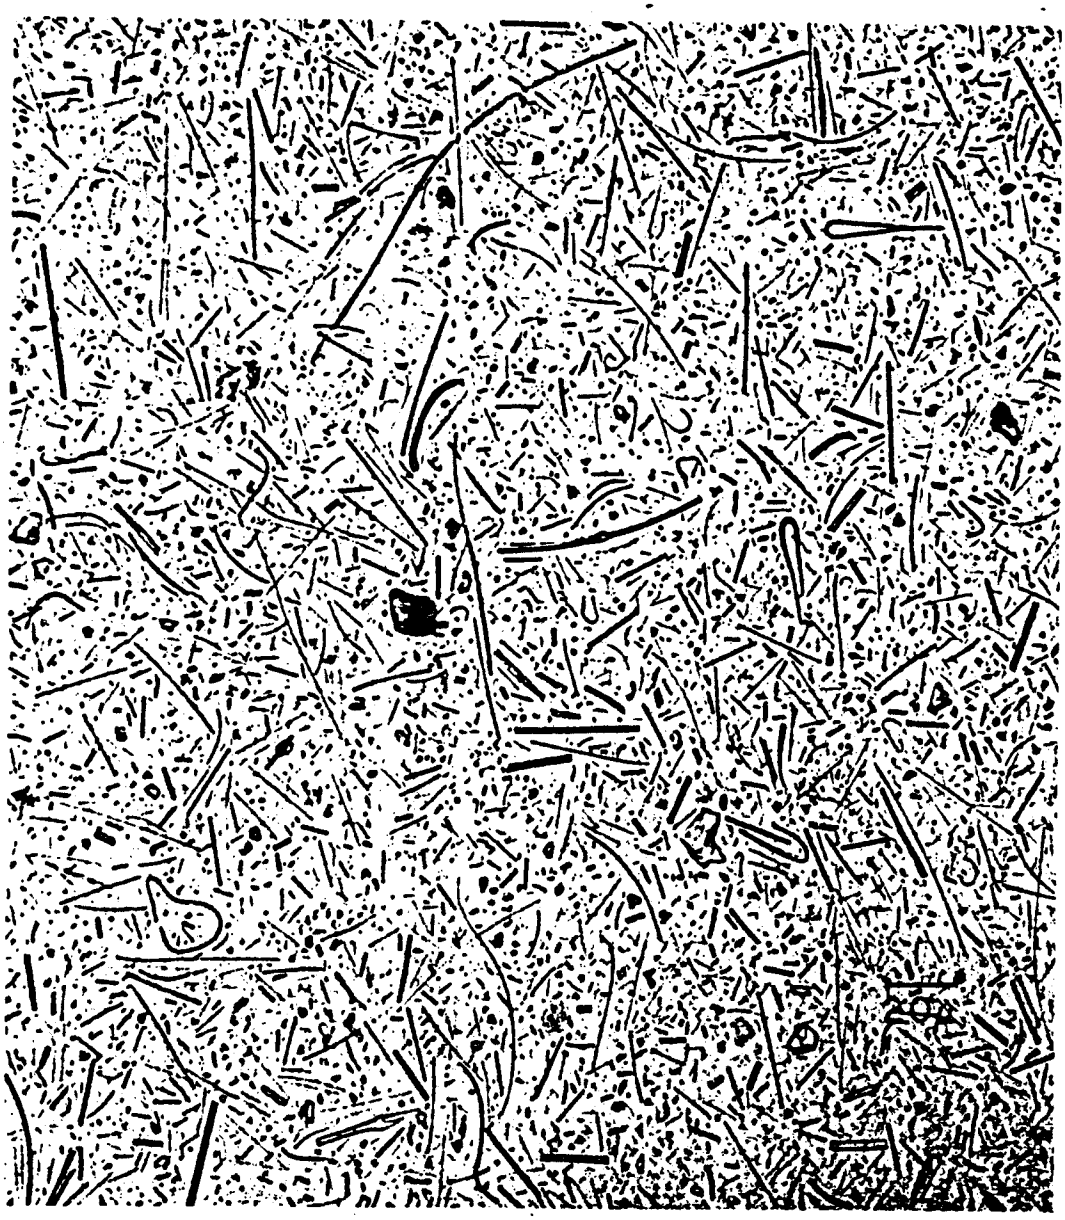

FIGURE 2. FIBER PRODUCED BY 3/4-HOUR BALL MILLING

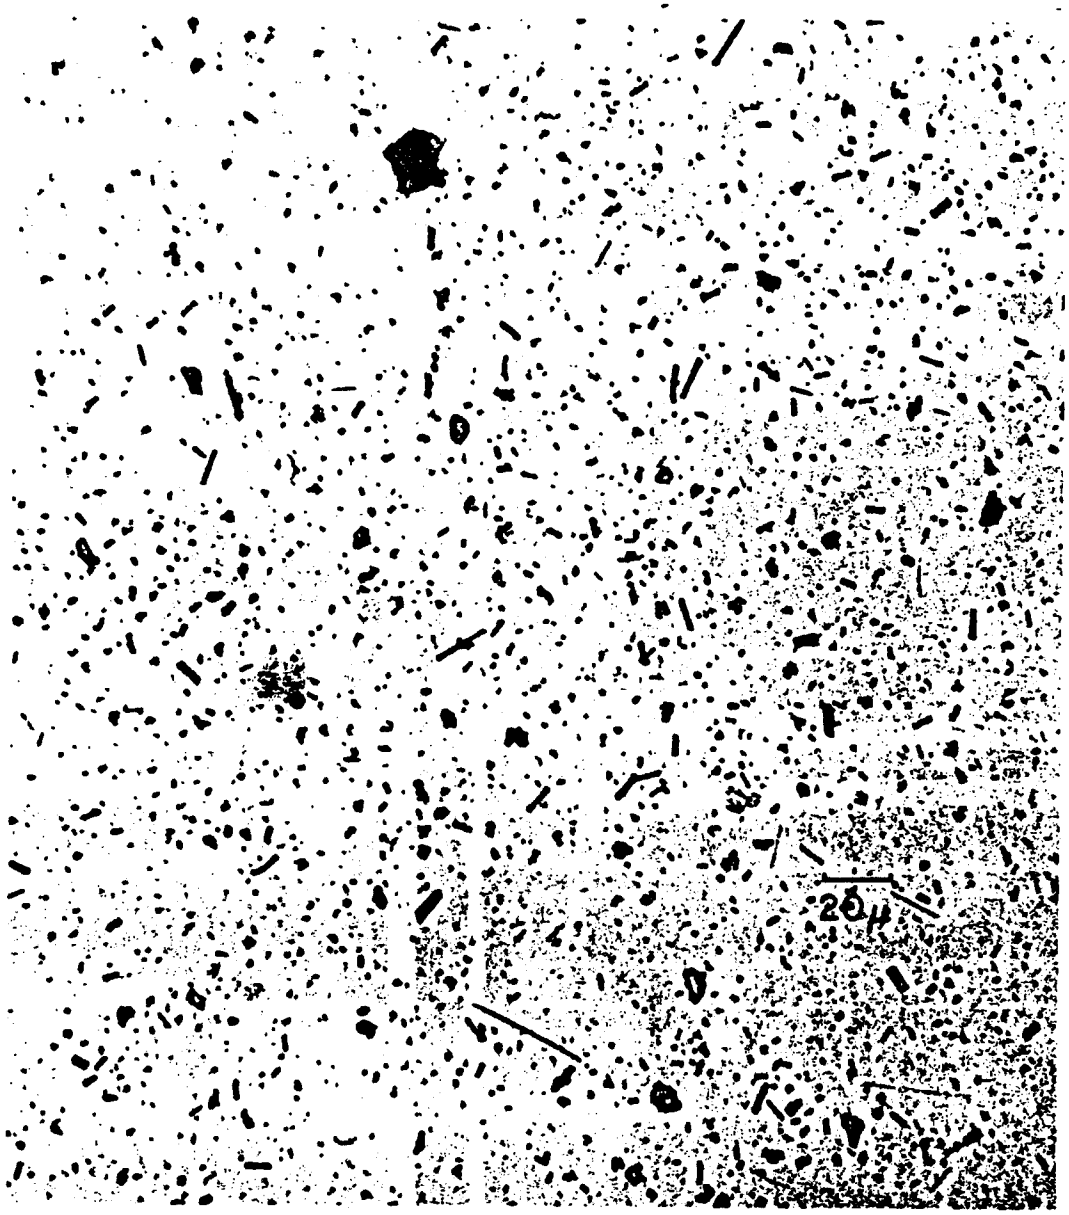

FIGURE 3. FIBER PRODUCED BY 2-HOUR BALL MILLING

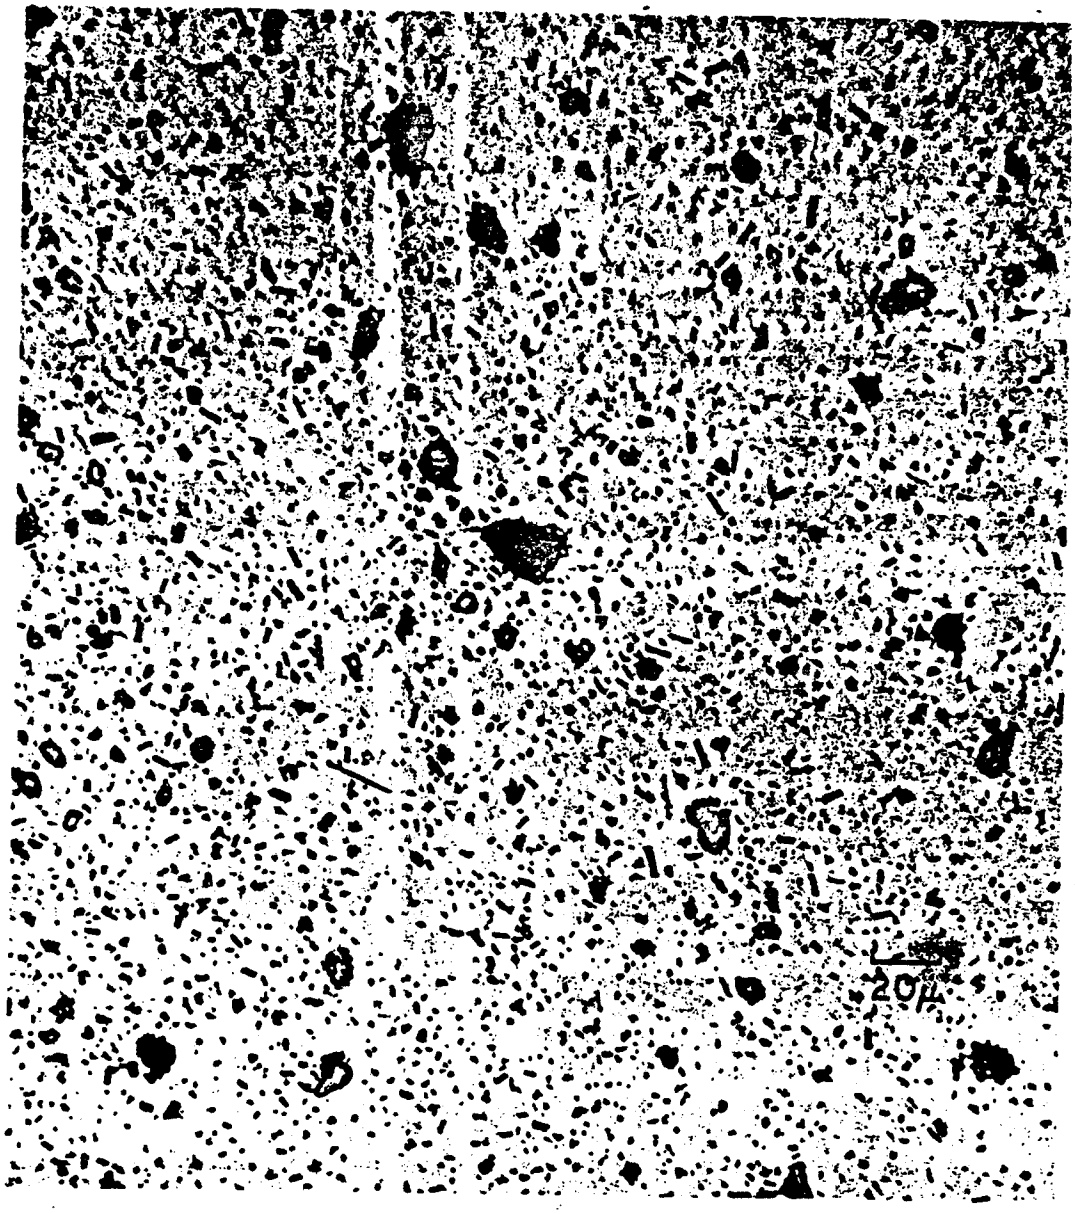

FIGURE 4. FIBER PRODUCED BY 4-HOUR BALL MILLING

High Speed Hammer Mill

The No. 5 Mikro Atomizer is a high-speed mechanical pulverizer that has a built-in air classifier. It generally produces particles in the range of 1 to 50 microns. The Mikro Atomizer might grind the 4 to 12 micrometer fibers if the fiber would clear the grinding chamber. However, cooling the fiber with dry ice failed to get the fibers to clear the grinding chamber and mixing the fiber with a hard resin to control the grinding failed. About 30 parts of fiber was hot blended with 70 parts of a hard resin, cooled, and ground. Low molecular weight Dow PS-SL-312 polystyrene* released the fiber too easily, and high molecular weight Dow 666-10 polystyrene was too tough to grind.

Ring Mill

The 4 to 12 micrometer FG Insulation Fiberglas with binder was ground successfully in a Willy Bleuler Apparatebau grinder. The Willy Bleuler has a set of three concentric solid and hollow cylinders that shake vigorously. The fiber length was reduced to approximately 20 microns in 30 seconds to 1 minute.

Figure 5 is a photograph of 200X magnification of 4 to 12 micrometer diameter fibers ground of 0.5 minute in the Willy Bleuler Apparatebau grinder. Longer grinding produced shorter fibers.

After the initial milling evaluations were completed, the Willy Bleuler Apparatebau grinder was selected for preparing all the fiber fractions required in the exposure program. A 30 second grind reduced the 4 to 12 micrometer diameter FG Insulation Fiberglas with binder to a mean length of about 20 micrometers. A 1 minute grind reduced the 1 micrometer diameter Tempstran Code 100/475 to a mean length longer than 10 micrometers, and a 3.5 minute grind reduced the 1 micrometer diameter Tempstran Code 100/475 fiber to a mean length of less than 10 micrometers. Grinding 1 micrometer diameter FM Series Air Filter Media with binder for 30 seconds produced fibers with lengths longer than 10 micrometers.

FIGURE 5. FIBER PRODUCED BY 0.5-MINUTE GRIND IN WILLY BLEULER APPARATEBAU GRINDER

Classification

All of the grinding techniques which produced glass fibers in the desired size ranges also produced large numbers of particles and fibers with length to diameter ratios smaller than 3 to 1 as well as a few fibers that were up to several hundred micrometers long. Further processing was necessary to remove undersize and/or oversize particles and fibers to meet the required sizes. Consequently, various techniques, including centrifuging, wet filtration, and settling techniques, were developed to remove the oversize and undersize fibers and particles.

Initially, about 3 grams of ground material was dispersed ultrasonically in about 300 ml of water and filtered through a 325 mesh sieve. The dispersion was stirred rotationally and the sieve was vibrated to prevent plugging. The long fiber was retained on the sieve. Following sieving, the filtrate was allowed to settle for about 1 hour and the supernatant liquid, which contained extremely fine fragments, was poured off. The process was repeated several times. Reduction of the fines in the product was evident; however, some fine fragments still remained even after 5 such washings. The fines removed by this treatment ordinarily remain suspended for days producing a milky supernatant liquid; but after each rinsing treatment, the supernatant cleared more rapidly. Significant upgrading of the fiber fractions was achieved, confirming the results reported in two recent studies at Johns-Manville[30] and at the Institut fur Aerobiologie[31].

Long fiber fractions were prepared from the settled fraction while the short fiber fraction was recovered from the supernatant. Additional washings prepared the four required fiber fractions as follows:

Fiber Fraction	Fiber	Production Method
L) 4 to 6 micrometer diameter fiber greater than 20 micrometers long with binder	4 to 12 micrometer diameter FG Insulation Fiberglas with binder	Ground for 0.5 minute, wet sieved through a 325 mesh sieve, washed twice to remove fines, collected on filter, and sieved to break up cake.
!) 0.5 to 3.5 micrometer diameter fiber greater than 10 micrometers long with binder	1-micrometer FM Series Air Filter Media with binder	Ground for 0.5 minute, wet sieved through 325 mesh sieve, washed 4 times to removes fines, collected on filter, dried, and sieved to break up agglomerates.
;) less than 3.5 micrometer diameter fiber greater than 10 micrometers long	1 micrometer Tempstran Code 100/475	Ground for 1 minute, wet sieved through 325 mesh sieve, washed 4 times to remove fines, collected on filter, dried, and sieved to break up agglomerates.
,) less than 3.5 micrometer diameter fiber less than 10 micrometers long	1 micrometer Tempstran Code 100/475	Ground for 3.5 minutes, suspended material filtered, dried, and sieved to break up agglomerates.

Figures 6 to 9 are photographs of these fiber fractions at 800X. One centimeter on the photographs represents 12.5 micrometers at 800X. Although the fibers in Figures 8 and 9 were from the same parent material, nominally 1 micrometer diameter fiber, the diameters of the fibers in the settled fraction in Figure 8 were significantly larger than the diameters of the fibers in the supernatant fraction in Figure 9. The same effect can be seen in the fibers in Figure 7 from the settled fraction of fibers from parent fibers with nominal diameters of about 1 micrometer.

Since this technique required extensive time, liquid and air elutriation methods were evaluated. In elutriation, the opposite of sedimentation, the upward flow of the liquid or air interacts with the normal settling of the fibers. The large fibers settle whereas the small fibers move upward with the classification media. Some success was achieved with this technique, but the time required to size a fiber fraction was not acceptable.

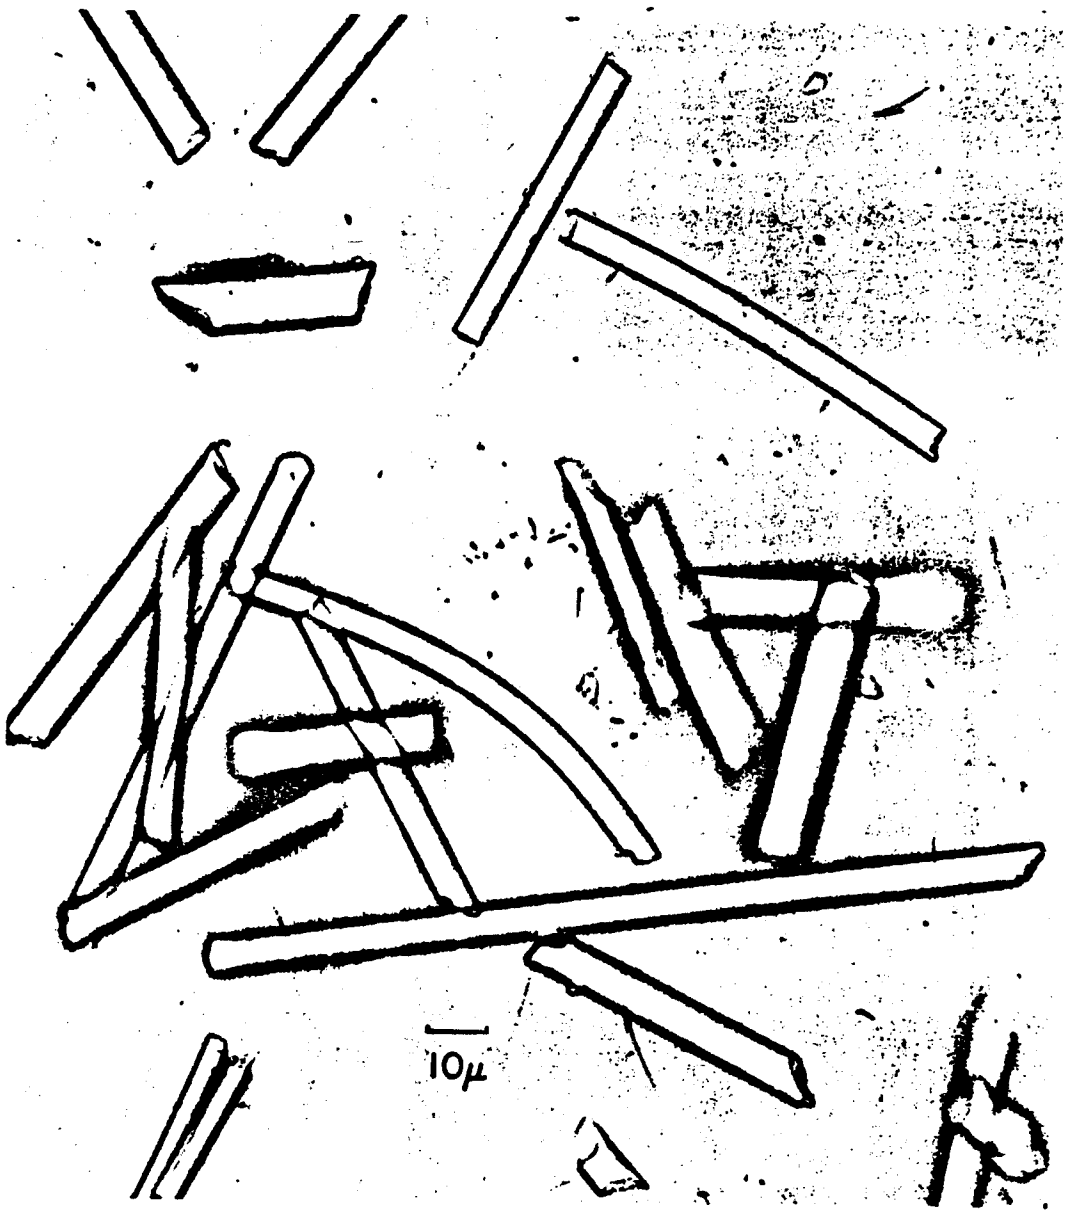

FIGURE 6. CHAMBER 1 FIBERS (800X)

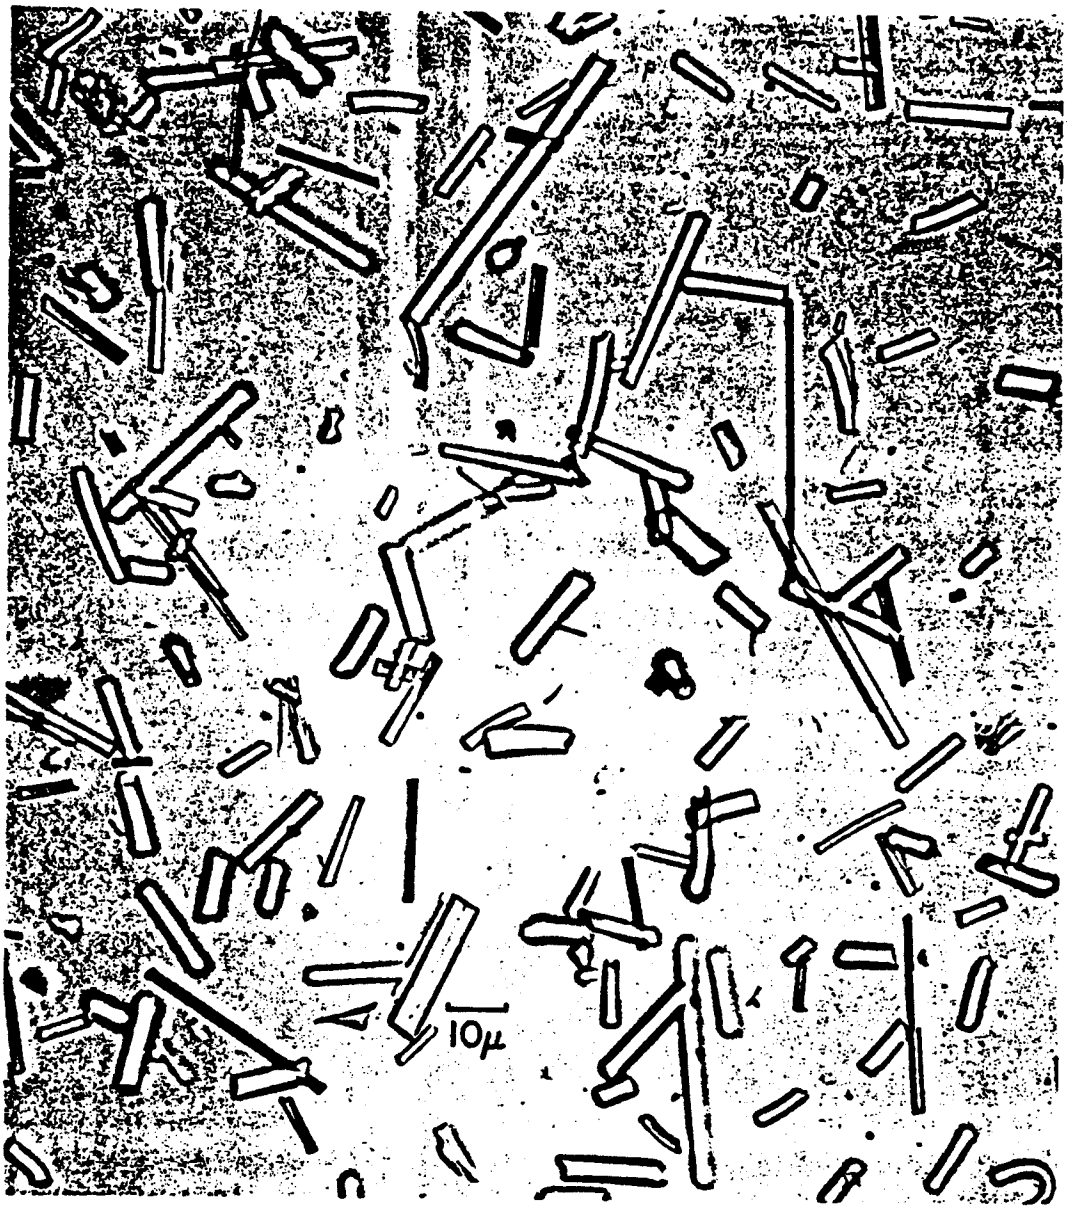

FIGURE 7. CHAMBER 2 FIBERS (800X)

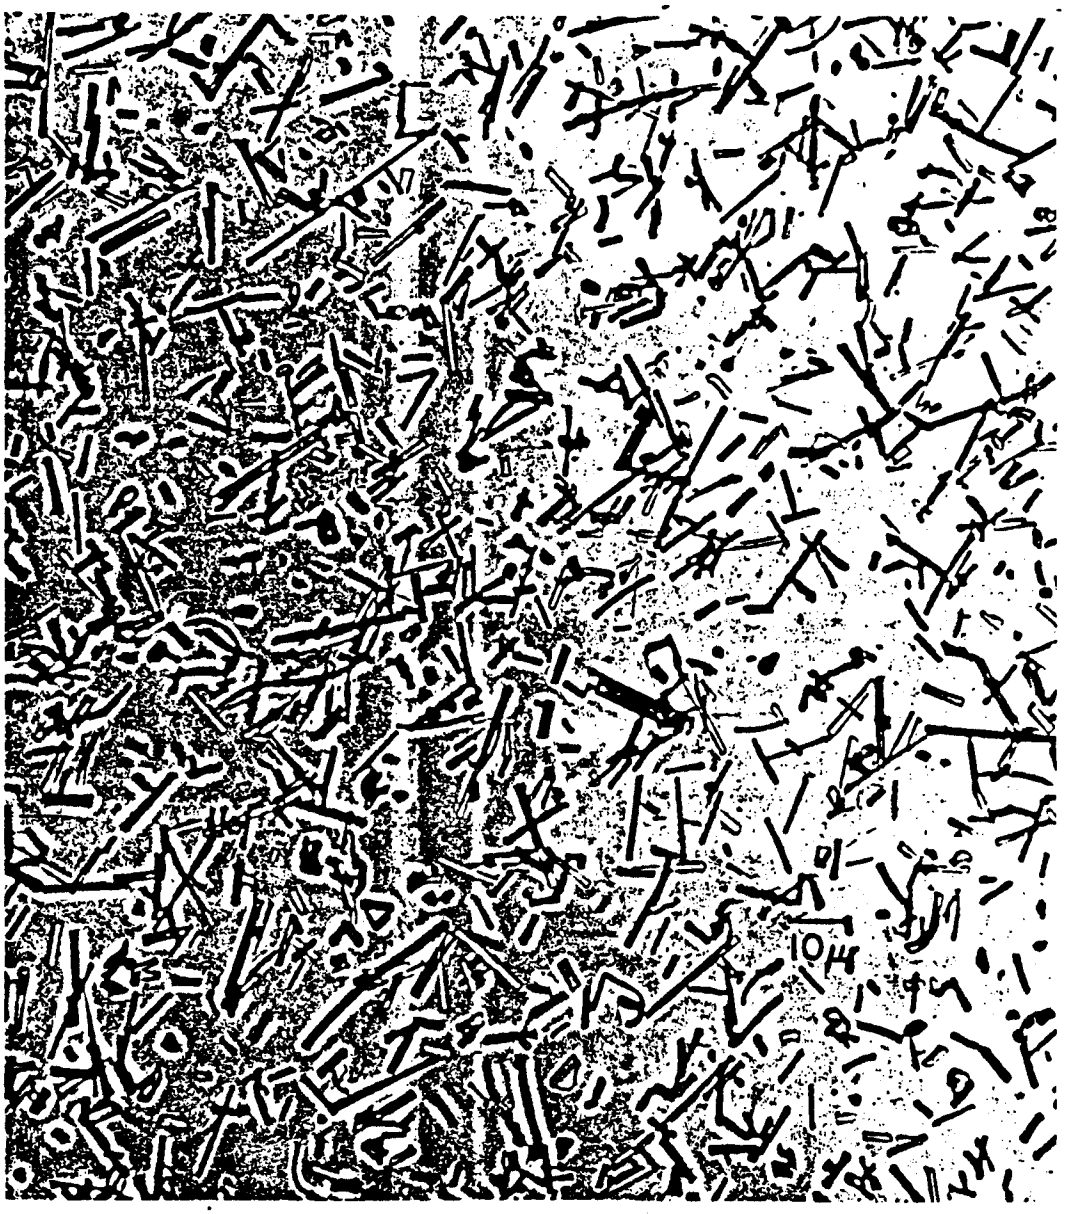

FIGURE 8. CHAMBER 3 FIBERS (800X)

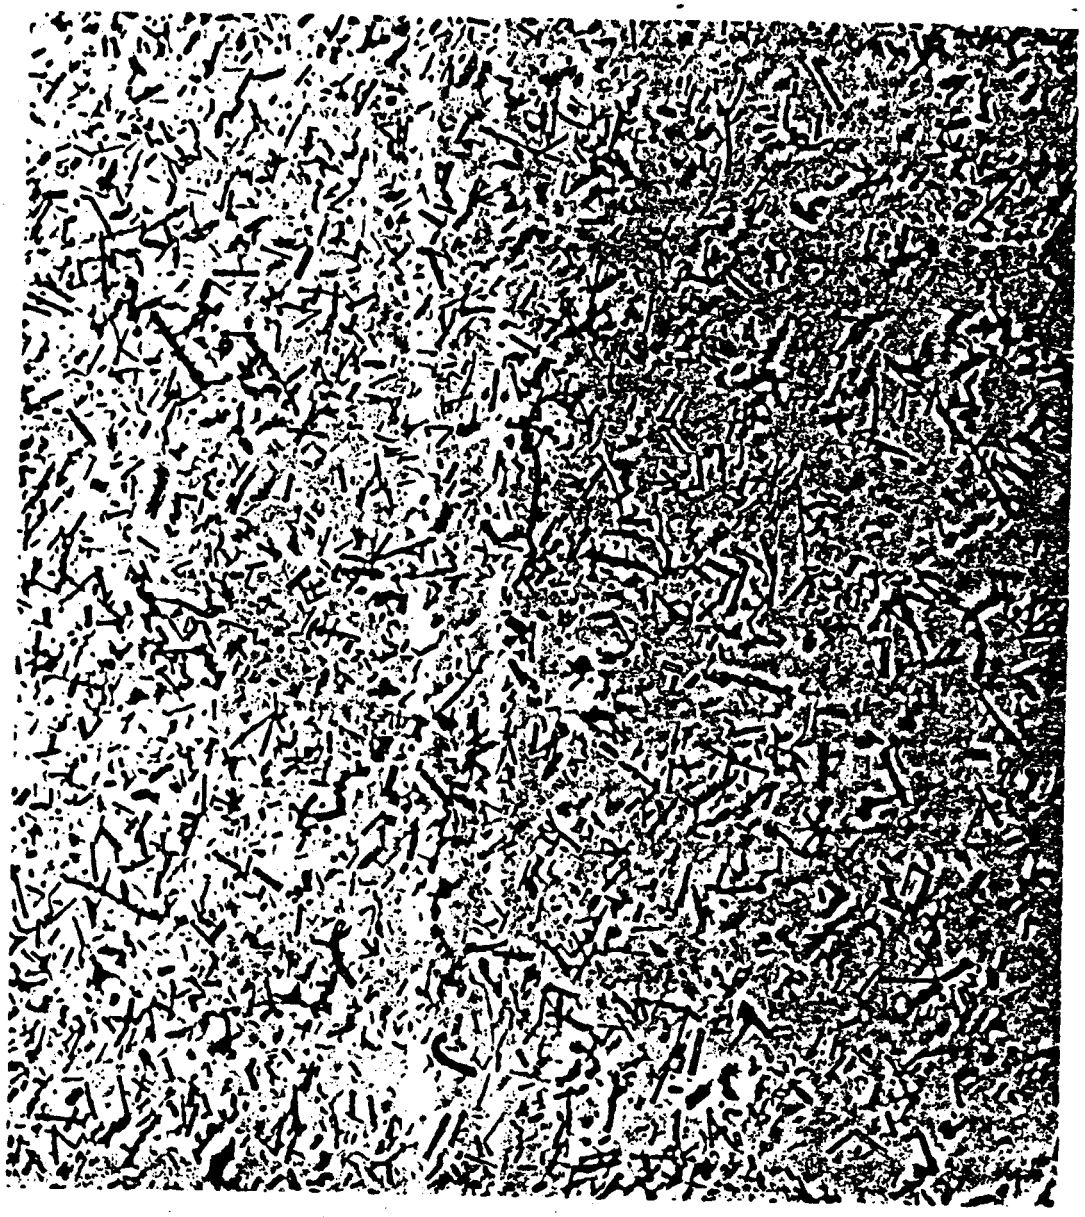

FIGURE 9. CHAMBER 4 FIBERS (800X)

Ultimately, a Bahco-Microparticle classifier* was used to increase the fiber production rate. The Bahco microparticle classifier (shown in Figure 10) is an air centrifuge-elutriator consisting of a rotor assembly driven by an electric motor. The motor and rotor are enclosed in a cast metal housing. The motor operates at 3500 RPM creating a precisely controlled air velocity within the air spiral and sifting chamber of the centrifuge. The sample is introduced into a spiral shaped air current flowing toward the center of the apparatus. The spiral current of air has suitable values of tangential and radial velocities so that a "heavy" portion of the sample is accelerated by the centrifugal force toward the periphery of the whirl. The "light" part of the sample is carried by the air current toward the center of the whirl by means of friction between the air and the powder particle. The size, shape, and weight of the particles determine which direction they take in the air current.

The Bahco successfully removed the oversize fibers from the FG Insulation Fiberglas and the oversize and undersize fibers from the FM Series Air Filter Media fibers. Attempts to classify the fine Tempstran fibers with the Bahco were not satisfactory.

After production started with the Bahco unit, work was undertaken with the larger capacity Donaldson Accucut (TM) Model 812 Air Classifier** with the objective of replacing the Bahco classifier in making the two fiber fractions with binders. In the Majac air classifier, fiber yield was about the same but the production rate was much higher than with the Bahco. Unfortunately, fiber breakage in the Majac reduced the fiber size significantly and the yield was too low.

Trials with the Majac air classifier also were run on the fine fibers which could not be fed into the Bahco. Production rates of about 11 kg of fiber per hour appeared to be possible; however, a single pass did not cut the fibers cleanly and a second pass did not duplicate the quality achieved by the wet separation process used for daily production.

** Majac Division, Donaldson Co., Inc., Minneapolis, Minn.

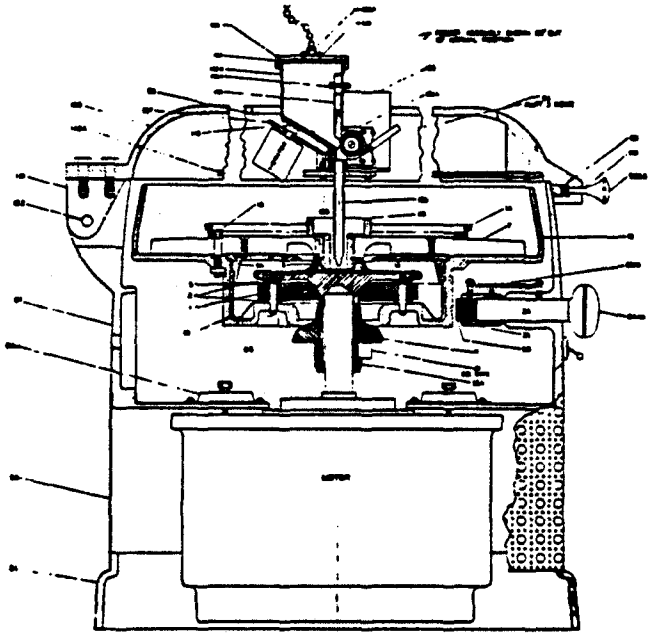

FIGURE 10. THE BAHCO MICROPARTICLE CLASSIFIER USED FOR THE DETERMINATION OF PARTICLE SIZE OF FINE DUST

Feeding the fine fibers also was a problem in the larger classifier.

However, liquid centrifuging was successful with the fine fibers. The centrifuge increased the daily production rate when used on fibers from the sieving and sedimentation tanks. After centrifuging for 1 minute at 1470 rpm, the < 10 μm fibers still were in suspension and the > 10 μm fibers settled. Trial separations were made with propanol, ethyl alcohol, and distilled water. Distilled water was selected for production use.

Table 2 summarizes the classification procedure for each fiber type used in the exposure program.

Fiber Production

Production of fibers was started with the Willy Bleuler mill to provide the daily deliveries of 40 grams each of the two fiber fractions with binders and 10 grams each of the two plain white fibers. Because the Willy Bleuler mill grinds only a 5 to 7 gram batch, studies were continued to find a mill with a larger capacity to reduce production costs.

Milling in a 12 inch diameter rod mill was attempted on the 1 micrometer FM Series Air Filter Media fiber with binder. However, milling with 0.25 to 1 inch diameter steel rods failed to produce significant yields of the required fiber lengths in wet grinds up to 1 hour.

Subsequently, a Planetary mill was evaluated. Batches up to 400 grams were ground in the Planetary mill in the same time that the 5 to 7 gram batches were ground in the Willy Bleuler mill. However, the fibers milled in steel jars were highly contaminated with iron from the mill and balls.

Jars with polypropylene and ceramic liners subsequently were used to reduce contamination of the fibers. The polypropylene liners were not satisfactory for grinding the fibers, but the porcelain liners ground the fibers apparently without contamination. Coating the mill with

TABLE 2. CLASSIFICATION TECHNIQUES TO PRODUCE SIZED FIBERS

	Fiber Fraction	Fiber	Production Method
(1)	4 to 6 micrometer diameter fiber greater than 20 micrometers	4 to 12 micrometer diameter FG Insulation Fiberglas with binder	Ground for 0.5 minute, wet sieved through a 325-mesh sieve, washed twice to remove fines, collected on filter, and sieved to break up cake. Undersized removed by Bahco.
(2)	0.5 to 3.5 micrometer-diameter fiber greater than 10 micrometers long with binder	1 micrometer FM Series Air Filter Media with binder	Ground for 0.5 minute, wet sieved through 325-mesh sieve washed 4 times to remove fines, collected on filter, dried, and sieved to break up agglomerates. Both undersize and oversize fibers removed by Bahco.
(3)	less than 3.5 micrometer diameter fiber greater than 10 micrometers long	1 micrometer Tempstran Code 100/475	Ground for 1 minute, wet sieved through 325-mesh sieve, centrifuged and settled material removed and resuspended, centrifuged again (process repeated 4 times). Fiber collected on filter, dried, and sieved to break up agglomerates.
(4)	less than 3.5 micrometer fiber less 10 micrometers	1 micrometer Tempstran Code 100/475	Suspended material from centrifuge of above separation settled for 24 hours. Settled fraction resuspended and filtered, dried, and sieved to break up agglomerates.

abrasive and impact resistant polyurethane produced the best results, however. Various combinations of grinding media were tried including steel balls, rubber covered steel balls, porcelain balls, and plastic rings and slugs. The steel or porcelain balls produced a 50 to 60 percent yield of the required size fraction in about 1 minute. The other media produced poor yields of usable fibers with 3 to 10 minutes of grinding. Several test grinds were made with polyurethane lined mills and the fibers appeared satisfactory.

However, before changing the grinding procedure to use the higher capacity planetary mills, a series of test grinds was run to compare the fibers made with the planetary mill with the fibers made with the Willy Bleuler mill as follows:

Type of Glass Fiber	Type of Grinder	Weight of Sample, gms*
FG Insulation Fiberglas	Planetary Mill	100
FG Insulation Fiberglas	Willy Bleuler	25
FG Series Air Filter Media with binder	Planetary Mill	90
FG Series Air Filter Media with binder	Willy Bleuler	20
< 10 micrometer Tempstran 100/475	Planetary Mill	80
< 10 micrometer Tempstran 100/475	Willy Bleuler	15
> 10 micrometer Tempstran 100/475	Planetary Mill	80
> 10 micrometer Tempstran 100/475	Willy Bleuler	15

*Weight of two mill grinds

Because the large FG Insulation Fiberglas is the most abrasive fiber, the iron and polyurethane analyses were made only in the FG Insulation Fiberglas with the following results:

Grinder	Contamination, percent	
	Iron	Polyurethane
Planetary Mill	0.1	0
Willy Bleuler Mill	0.3	0

The iron contamination was measured with optical emission spectrography whereas the polyurethane analysis was made by IR. No evidence of urethane was detected with a sensitivity of about 1 percent. Iron contamination was lower in the fibers ground in the planetary mill than in fibers ground in the Willy Bleuler mill.

Tables 3 and 4 provide data comparing length distributions in the four fiber fractions made by the standard classification procedures following grinding in the Willy Bleuler mill or in the planetary mill. The size distributions essentially were equivalent and/or the mass distributions were satisfactory for use in the program by either method of grinding.

Comparisons of the contamination levels and length distributions in the fibers indicated that the products made by grinding in the planetary mill and Willy Bleuler mill were equivalent.

Production of fibers for the exposure program was began in October, 1980, following approval by NIOSH.

Quality Control

Quality of the fibers was characterized at each step of the production and each lot of fiber delivered to the animal facility was examined. If any discrepancy in the fiber size distribution was noted, the lot was rejected and another lot was sent for the inhalation studies.

Daily evaluations were performed with a Lietz optical microscope with a micrometer eyepiece for fiber measurement. Fibers were examined

*Calculated from number distributions determined by counting 100 to 500 fibers.

at 100, 500, and 1000X. The fibers were commercial production products, and variations in the diameters were noted early in the program. Classification to reduce the amount of oversize diameter fibers usually was successful, but the fiber diameters were variable. Some lots of fibers were rejected because the diameters did not meet the specifications. Figures 6 - 9 are 800X photographs of several typical lots of glass fiber fractions supplied to the animal laboratory for inhalation exposures.

During the program, fiber counts were made on several lots of production fibers using the Lietz optical microscope or a scanning electron microscope. The fibers were photographed and measured with an optical digital analyzer.

Archive lots were retained on a daily basis throughout the program. At the end of the exposure program, randomly selected samples of fibers were examined. The selected samples were used in the exposure program during the period from November 26, 1980, to December 19, 1980. Approximately 200 to 216 fibers were measured on photographs taken under magnification at 500X, and the mass distributions were calculated.

Data in Table 5, which summarize the measurements shown in Tables 6 - 9, indicate that approximately 91 to 99 percent of each type of fiber by weight was in the required size range. The target was a minimum of 80 percent by mass in the desired size range. Thus, the quality of the fibers was satisfactory.

Tables 10 - 13 give particle size distributions made from SEM photographs of other lots of fiber which were used in the four chambers. Figures 11 - 14 are three-dimensional plots of this data.

Fiber Aerosol Generation

Each type of glass fiber was unique in handling characteristics and aerosols ultimately were generated in a manner best suited for each type of fiber. Basically, the generation system consisted of a metering device, a dispersing mechanism, and a delivery system.

Various feeders were considered at the beginning of the program and a bead chain design initially was selected as the best method of providing the required low feed rates. The fibers were dispersed with an air venturi and delivered via a 1/2-inch diameter Tygon tube to the center of the air circulation inlet duct in the cupolas of the chambers. Problems immediately developed in achieving the desired concentrations in the chambers, especially in Chambers 1 and 2 where the higher concentrations of fibers with binders were required. Much of the problem resulted from static charge on the fibers that caused the fibers to deposit on the walls of the delivery tubes and on the walls at the entrance of the cupolas. Feed rates of 7 to 10 times the theoretical rates were necessary to achieve the required concentrations. Radioactive and corona-type static eliminators were installed to reduce the charge on the fibers but the use of static eliminators was discontinued because of possible secondary effects that the radiation, ozone, and ions might have had on the test animals.

The bead chain feeders in Chambers 1 and 2 were replaced with two-fluid atomizers on May 4, 1979. Dispersions of 20 grams of fiber per 100 ml of water were sprayed in short pulses followed by an evaporation period with no significant increase in relative humidity in the chambers.

Wear on the bead chain feeders in Chambers 3 and 4 required increasing operator attention as the study proceeded, and on January 31, 1980, the bead chain feeders were replaced with improved rotary platform feeders. The performance of these feeders was excellent, and the two-fluid atomizer on Chamber 2 subsequently was also replaced with a rotary platform feeder on June 11, 1980, with a reduction in the use of material and need for operator attention. Although the rotary platform feeder also worked on the fiber used in Chamber 1, material requirements were about the same; consequently, the spray system was not changed on Chamber 1.

Bead Chain Feeder

The bead chain feeder design was based on the bead chain meter system described by Marple et al.[32] A venturi aspirator dispersing system was incorporated to avoid loss of fibers in the fluidized granular bed used with the Marple unit.

After several modifications, the design for the fiber aerosol generator was finalized as shown in Figure 15. A bead chain feeds the fibers from the bottom of a conical supply chamber to a venturi aspirator which disperses and fluidizes the fibers. The fluidized fibers are passed through a small cyclone which contains a few 300 to 400 micrometer glass beads or 0.15 cm steel balls to break up or remove agglomerates before passing to the exposure chamber. A 0.3 cm diameter plastic bead chain was used originally; however, it was replaced with a similar metal chain because the plastic chain was too stiff and the end splices failed.

The hopper was vibrated to make the fiber flow into the bead chain reliably. Other approaches, such as mixing the fiber with fine carrier beads, were also tried and discarded. In the fiber bead approach, the carrier beads were collected in the cylcone for reuse. However, metal carrier beads bound in the Teflon lining around the feed tube and the fibers would not mix with glass beads unless the beads were resin coated. The coating on the glass beads deteriorated rapidly in the cylcone. A metal cyclone was used originally and the glass fiber stuck on the metal. Subsequently, the metal cyclone was replaced with a glass cyclone.

Water Spray System

To overcome static charge problems produced by the mechanical methods of feeding the fibers with binders, a system for spraying a water dispersion of fibers was developed for use in Chambers 1 and 2.

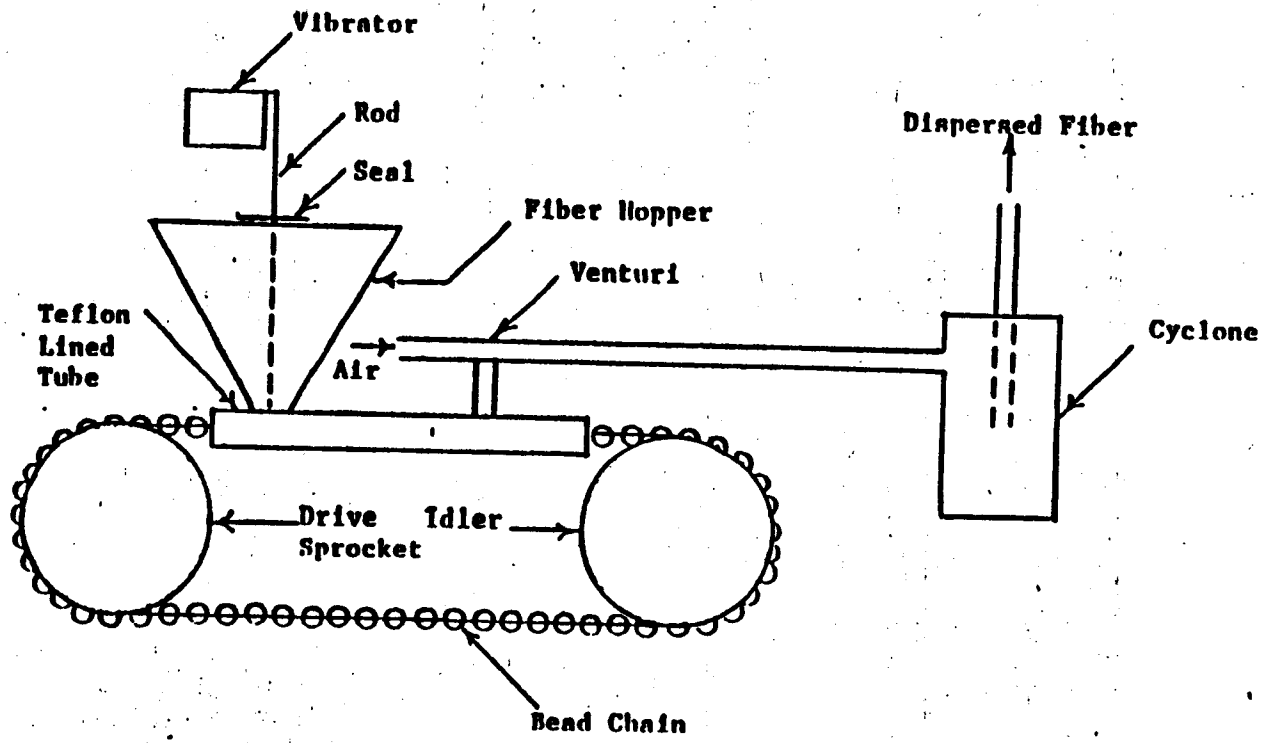

FIGURE 15. AEROSOL GENERATOR

Several spray systems and a nebulizer were tested before selecting a pulsed-type two-fluid atomizer with a cleaning system to prevent plugging of the nozzle.

The atomizer was a Spraying System Company's two-fluid atomizer with a No. 64 air nozzle and No. 1250 fluid body. Each sprayer was equipped with a No. 11829 Clean Out Needle Attachment operated with a solenoid on a cycle timed with the spray pulse. The sprayers operated with a siphon head drawing the fiber dispersion from a 600 ml reservoir below the sprayers. The fiber dispersion was agitated constantly with a magnetic stirrer to keep the fibers in suspension. The sprayers were located in the upper center of the chambers with the nozzles pointed toward the top of the chamber. Initially, the air was circulated with a fan in the top of the chambers to level out the fiber concentration in the chambers, but the use of the fan was discontinued as unnecessary after extensive studies were made of the fiber distribution in the chambers. Fiber concentration in the dispersion, air pressure, liquid flow rate, and pulse rate were adjusted to achieve the desired fiber concentration in the chamber with a minimum amount of water and fiber. Sufficient dilution of the dispersion avoided spraying groups of fibers in individual drops that form agglomerates when the water evaporates. At the same time, the amount of water sprayed was low enough that it did not raise the relative humidity in the exposure chamber more than 2 percent. The required concentrations of 15 mg/m^3 were achieved by spraying a dispersion of about 0.05 grams of fibers per ml of water with about 0.4 ml of Tween 80 dispersing agent per 100 ml of water to suspend the fibers. The sprayer system was operated by a timer that provided seperate control of the spray period from 1 to 10 seconds at 1 to 30 cycles per minute whereas the clean out needle was cycled for 1 second at 1, 2, 4, or 8 times per minute as needed.

Rotary Platform Feeder

By the end of the exposure program, rotary platform feeders such as shown in Figures 16 and 17 were used in Chambers 2, 3, and 4. The feeder consists of a 3 inch diameter by 6 inch cylindrical hopper positioned

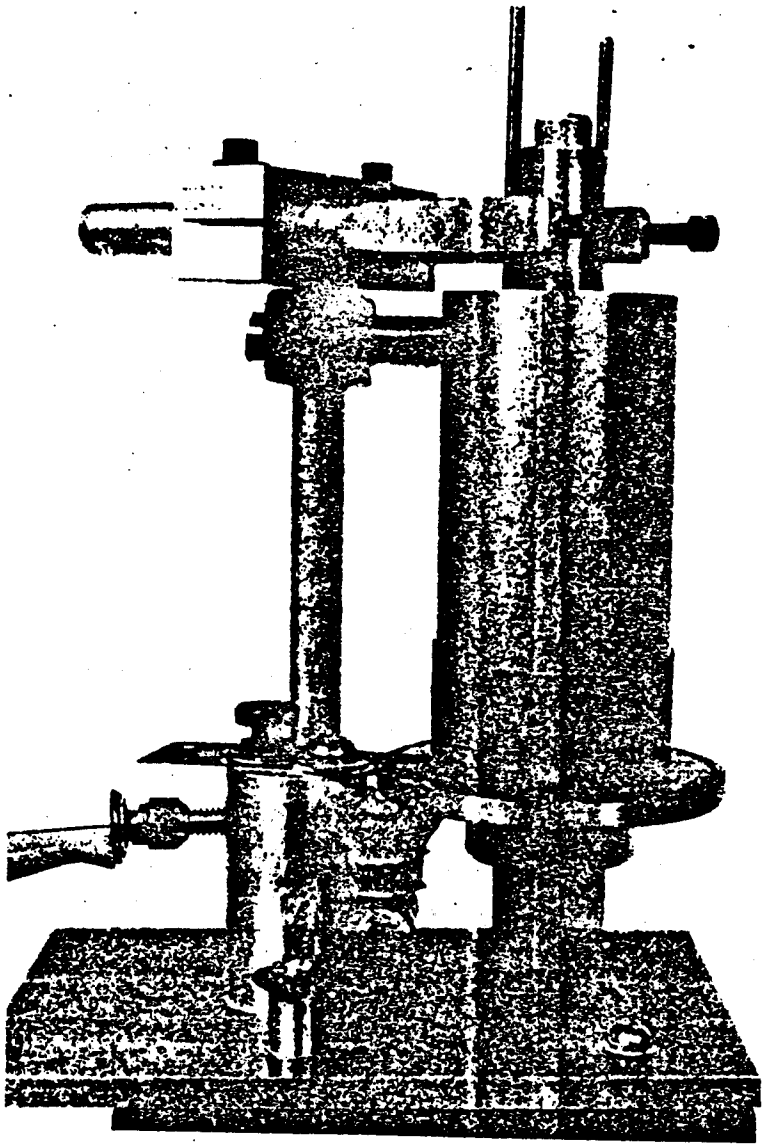

FIGURE 16. ROTARY PLATFORM FEEDER

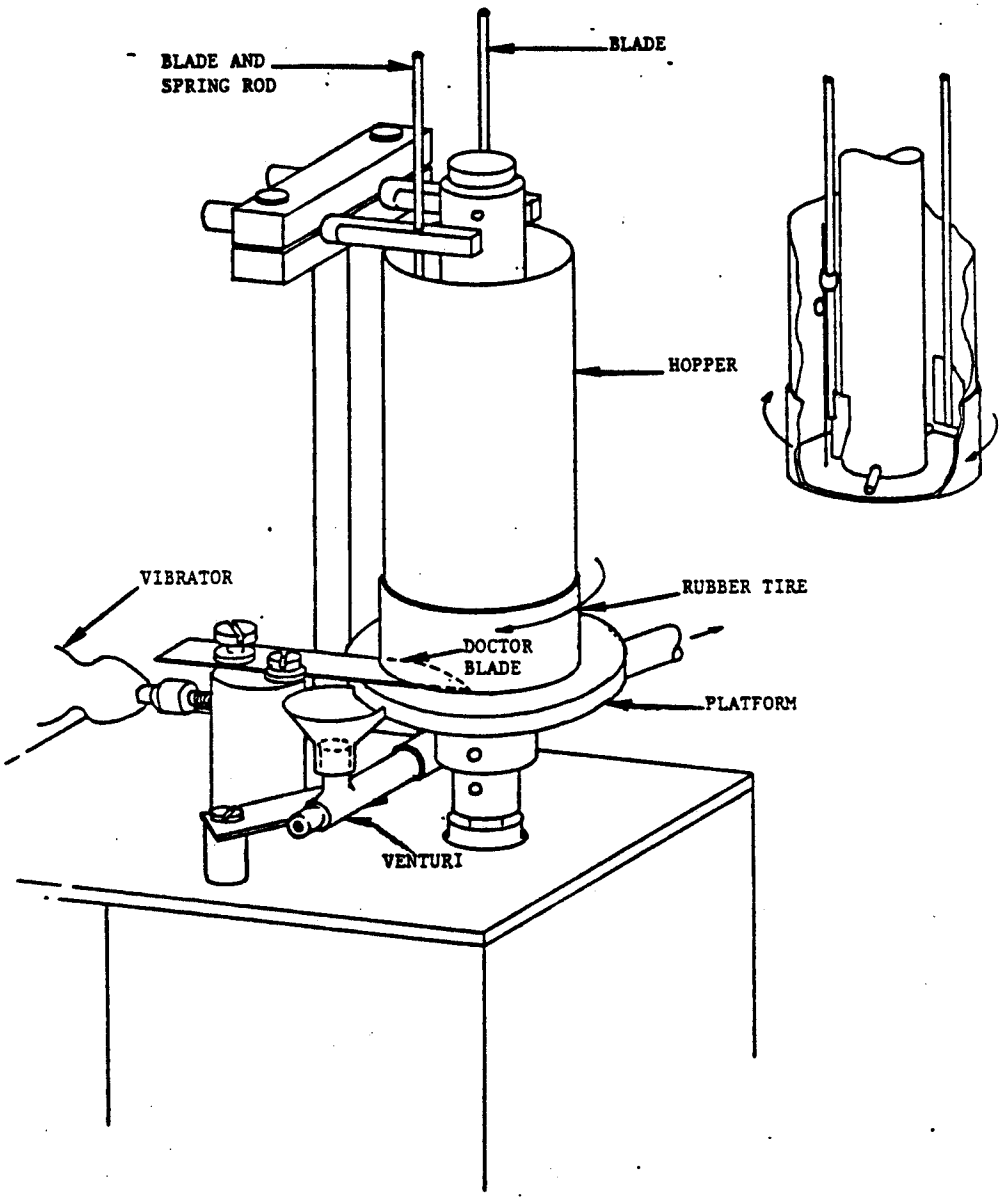

FIGURE 17. DETAILS OF ROTARY PLATFORM FEEDER

above a flat disc-shaped platform. As the cylinder and platform rotate, a thin ribbon of fiber is sliced out of the bottom of the hopper and moves along the edge of a doctor blade that is inserted between the platform and the cylinder. The gap between the hopper and the platform is covered by a rubber tube to prevent leakage of fiber except along the blade. The fiber eventually drops off the edge of the platform into a small funnel where the fiber is aspirated into an air venturi that disperses the fibers and injects the fiber through a 1/2-inch diameter Tygon tube to the inlet of the exposure chamber.

As the feeder rotates, two stirring blades and a spring rod inside the hopper stir the fiber to prevent bridging and move the fiber away from the center post and inner wall of the tube. The doctor blade was vibrated continuously with a small electric vibrator mounted on the doctor blade base.

The feeders were driven with Bodine* Model 533 motors and Bodine* D-C Motor BSH-200 Speed Controls.

Problems

With the bead chain feeders mounted outside the chambers, the required aerosol concentrations of 5 mg/m^3 and 15 mg/m^3 were achieved initially with chain speeds of 1-1/2 beads per minute and 5 beads per minute, respectively. However, the concentration dropped gradually in subsequent tests. Fiber accumulated in the 1/4-inch diameter Tygon tubing between the cyclone and the chamber and gradually slowed the airflow to the point that the aspirator did not pick up all of the fiber from the beads. To correct this problem, the venturi orifice was enlarged to pump more air through the cyclone and Tygon tube, but fiber disposition continued to be a problem.

In all the chambers, 5 to 10 times the calculated amount of fiber was required to achieve the fiber concentration desired in the chambers. Significant charge levels were detected in the chambers with an electrometer probe and large amounts of fiber were deposited on the walls at the entrance to the chamber. Various approaches were tried to stop the deposition including (1) lining the upper portion of the chamber with 10-mil Mylar to build a charge layer that should eventually repel additional charged fiber, (2) passing the

* Made by Bodine Electric Company , Chicago, Illinois 60618

fiber through a tube lined with a 10-millicurie radioactive source to produce ions to neutralize the charge on the fiber, and (3) discharging the fiber at the inlet with ions produced by AC or opposite polarity DC corona from a needle-type ionizer. Although the charge level in the chamber was reduced to zero at times, the fibers with binders still deposited on the walls at the entrance of Chambers 1 and 2.

The feeding problem was especially severe in Chamber 1 where the 4 to 6 micrometer diameter fiber greater than 20 micrometers long was used. Excessively high feed rates were necessary to achieve the desired concentration and the composition of the fiber shifted in the chamber. Static charge apparently deposited the long fibers on the chamber walls in the entrance area. Radioactive and AC and DC corona-type static eliminators were used to neutralize the charge on the fibers but the wall deposition continued. Because the extremely strong radioactive eliminators or high levels of corona that appeared to be necessary might alter the exposure environment, the use of a mechanical-pneumatic feed system was discontinued on Chamber 1 as well as on Chamber 2 where th problem also occurred. The bead chain feeders were replaced with two fluid atomizers mounted inside Chambers 1 and 2. The atomizers were positioned vertically upward and at a level so that the spray fan formed fully before reaching the cupola of the chamber where the fibers were mixed with the fresh air coming into the chamber. Although fiber deposition on the walls in and around the walls of the cupola was significant, the fiber length distribution delivered to the chamber did not shift and the fiber deposition was compensated by increasing the spray rate accordingly. Fiber was recovered from the walls and reprocessed for reuse.

The sprayer systems required frequent operator attention. The fiber delivery rate varied with the siphon height as the level in the feed reservoir dropped during the daily exposure period. The spray period and number of cycles were adjusted frequently each day. The large glass fibers caused extensive wear of the nozzles and clean out needles. Whenever the clean out needles jammed or broke, the large fibers quickly plugged the nozzles.

In contrast, the rotary platform feeders were very reliable and required a minimum amount of operator attention. Rarely, one of the spring stirring rods broke but no other maintenance was required. Speed adjustments were made and the hoppers were filed with fresh fibers on a daily basis.

Factors such as moisture content of the fiber as supplied and moisture pickup on the fiber during handling of fibers were considered as possible causes of feed rate variation. Although low moisture content caused problems with static electricity, high moisture content also appeared to cause the fibers to agglomerate in the feeders. These problems were not significant at the normal relative humidity in the exposure area. The fibers were transported and stored in glass jars with the lids tightly closed to maintain their condition in the fiber production operation and to avoid accidental moisture pickup or loss before use.

Exposure Groups

The study involved five groups of animals, including four exposure groups and a control group. The exposures were conducted in 5.4 m^3 chambers with air circulation of 1 m^3/min. Exposure conditions were as follows:

Chamber	Fiber	Concentration, mg/m^3
1	4 to 6 micrometer glass fiber >20 micrometer long with red binder	15
2	0.5 to 3.5 micrometer glass fiber >10 micrometer long with yellow binder	15
3	<3.5-micrometer glass fiber >10 micrometer long	5
4	<3.5-micrometer glass fiber <10 micrometer long	5
5	Control	0

Exposures of rats began in all chambers on March 12, 1979. Exposures of monkeys were delayed until the correct exposure concentrations had been maintained in the chambers for 5 consecutive days. Exposures of the monkeys were initiated at weekly intervals during June and July. Exposure of the last test group started on July 17, 1979. The exposure conditions were approved by NIOSH before the monkeys were put in the chambers.

Exposures of the monkeys were initiated on the following schedule:

Group	Chamber	Starting Date
V	5	6-19-79
IV	4	6-26-79
III	3	7-03-79
I	1	7-10-79
II	2	7-17-79

The temperature in the exposure area and chambers was maintained at 68.8 $\pm$ 1.9° F and the relative humidity at 50 $\pm$ 6 percent throughout the exposure period.

Chamber Monitoring

Aerosol quality was monitored in each chamber at least twice daily by mass samples drawn at 10 ℓ/m and collected on 0.45 micrometer Metricel DM450 filters in 47 mm Gelman holders*. Uniformity of the aerosol was sampled at various locations within the chambers with the mass samplers and with a Sinclair Phoenix photometer. Mass distribution in each chamber also was measured with a cascade impactor once each week. Samples were collected from the chambers with electrostatic samplers of various types. Size distribution in the material collected was examined periodically by observation under 350 to 500 X magnification.

Mass samples were taken with open faced 47 mm Gelman* filter holders which were mounted on 1/4-inch diameter steel tubing so that the samples could be inserted through ports in the front of the chambers on each side of the doors and held in various positions from the front to the rear of the chambers. Air was drawn through the filters with vacuum pumps, and flow was controlled with critical flow orifices. Initially, silver membrane filters were used, but the samples collected on the high density filters created a pressure drop which occasionally affected the critical flow conditions during the 30 minute sampling period. Although the high density filters appeared to be satisfactory for 15 minute sampling periods, a change was made to Metricel DM450 filters

* Gelman Instrument Company, Ann Arbor, Michigan 48106

which were satisfactory for 30 minute sampling periods. The filters were moisture conditioned and weighed with a Metler 52 microbalance* under constant humidity conditions in the animal facility. The filters were weighed by a procedure that provided a weighted average precision of about 27 micrograms.** The sampling rates were checked periodically with a wet test meter.*** Table 14 lists the actual flow rate of the sampling orifices.

Before the animal exposures were begun, uniformity of the fiber concentration in the chambers was measured by sampling at various positions along each side of the chamber and over the animal cages in the chambers. Samples were taken at the front, center, and back of the chamber at the level of the upper animal cages and the level of the lower animal cages.

Size distribution of the fibers in each of the exposure chambers was measured at least once a week with a cascade impactor**** shown in Figure 18. The impactor was placed inside the chambers and chamber air was drawn through the impactor with a vacuum pump at a rate of 1 cfm for 30 minutes. Theoretically, the cascade compactor should be capable of measuring the aerodynamic characteristics of a fiber glass aerosol. (See Appendix F for a discussion of inertial characteristics of fibers.) This capability was verified by measuring fibers collected on three successive stages of a well calibrated specially designed Battelle impactor from Chamber 2. Tables 15 through 17 list the measured diameter and length, fiber aspect ratio, and calculated impactions equivalent diameter for each fiber size. The particle size distribution based on impaction equivalent diameters is shown in Figure 19. This plot shows that the cut-off sizes***** for the stages are 6.6 and 3.5 μm as compared to 5.7 and 2.8 μm for spheres with a density of 2.0. The fibers for these chambers were covered with a yellow phenol formaldehyde coating and depending upon the thickness of the coating could have

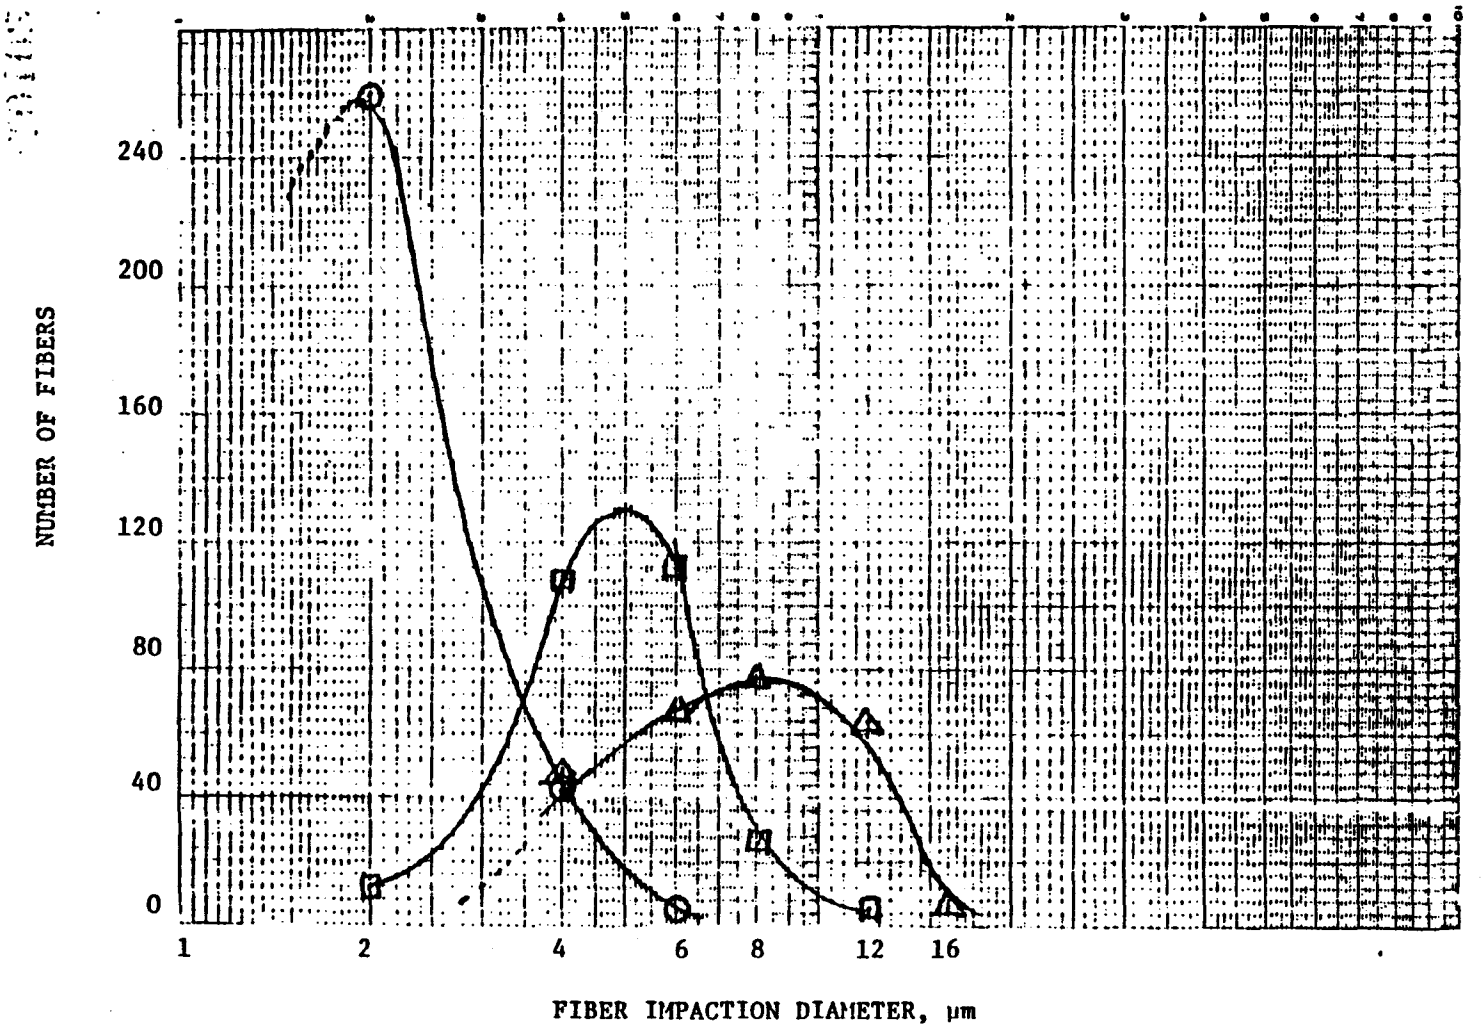

FIGURE 19. PARTICLE SIZE DISTRIBUTION OF GLASS FIBERS OBTAINED WITH A BATTELLE CASCADE IMPACTOR

a lower density. This correlation indicates that a cascade impactor can characterize fibers reasonably well. The major problem with using any type of an instrument to characterize an airborne fiber glass cloud is electrostatics. Total mass collected on the impactor stages were generally less than 10 percent of the mass concentration in the chambers from entrance losses due to the electrical charge on the fiber. Figures 20 through 23 are typical particle size distribution obtained with the cascade impactor. It was found that the impactor could show considerable particle size variation from week to week even though the particle size characteristics of the fiber glass before generation was constant. Some of this variation was due to the accuracy of weighing the impaction stages; however, electrostatics seemed to be the primary cause. The large red fibers which were coated with binder had inertial characteristics so that most of an impactor sample should have collected on the first impaction stage however, none of the extremely large charged fibers failed to reach the impaction surface. Therefore, the only material that deposited on the impactor stages were small fibers, fragments of the layer fibers, and fragments of the binder which were dislocated during powder cloud generation.

To further confirm if the impactor was suitable to characterize power clouds of smaller fiber particle size measurements were made with a scanning electron microscope of bulk powder used in Chamber four.* Similar measurements were made of fibers collected on filters from Chamber four. Table 18 summarizes the particle size measurements. The impaction equivalent diameter and volume of each particle was then calculated. The weight percentage in each size class was then plotted to obtain a cummulative mass distribution as shown in Figure 24. A typical impactor particle size distribution obtained from Chamber four is shown in Figure 23. These figures show that the mass-median impactor equivalent diameter of the filter sample is 1.8 μm and the mass-median impaction diameter taken with the cascade impactor is approximately 1.6 μm. This indicates a close agreement between the impactor and filter samples.

* Microfibers without binder less than 10 μm in length.

*< 3.5 μm in diameter - < 10 μm in length - no binder

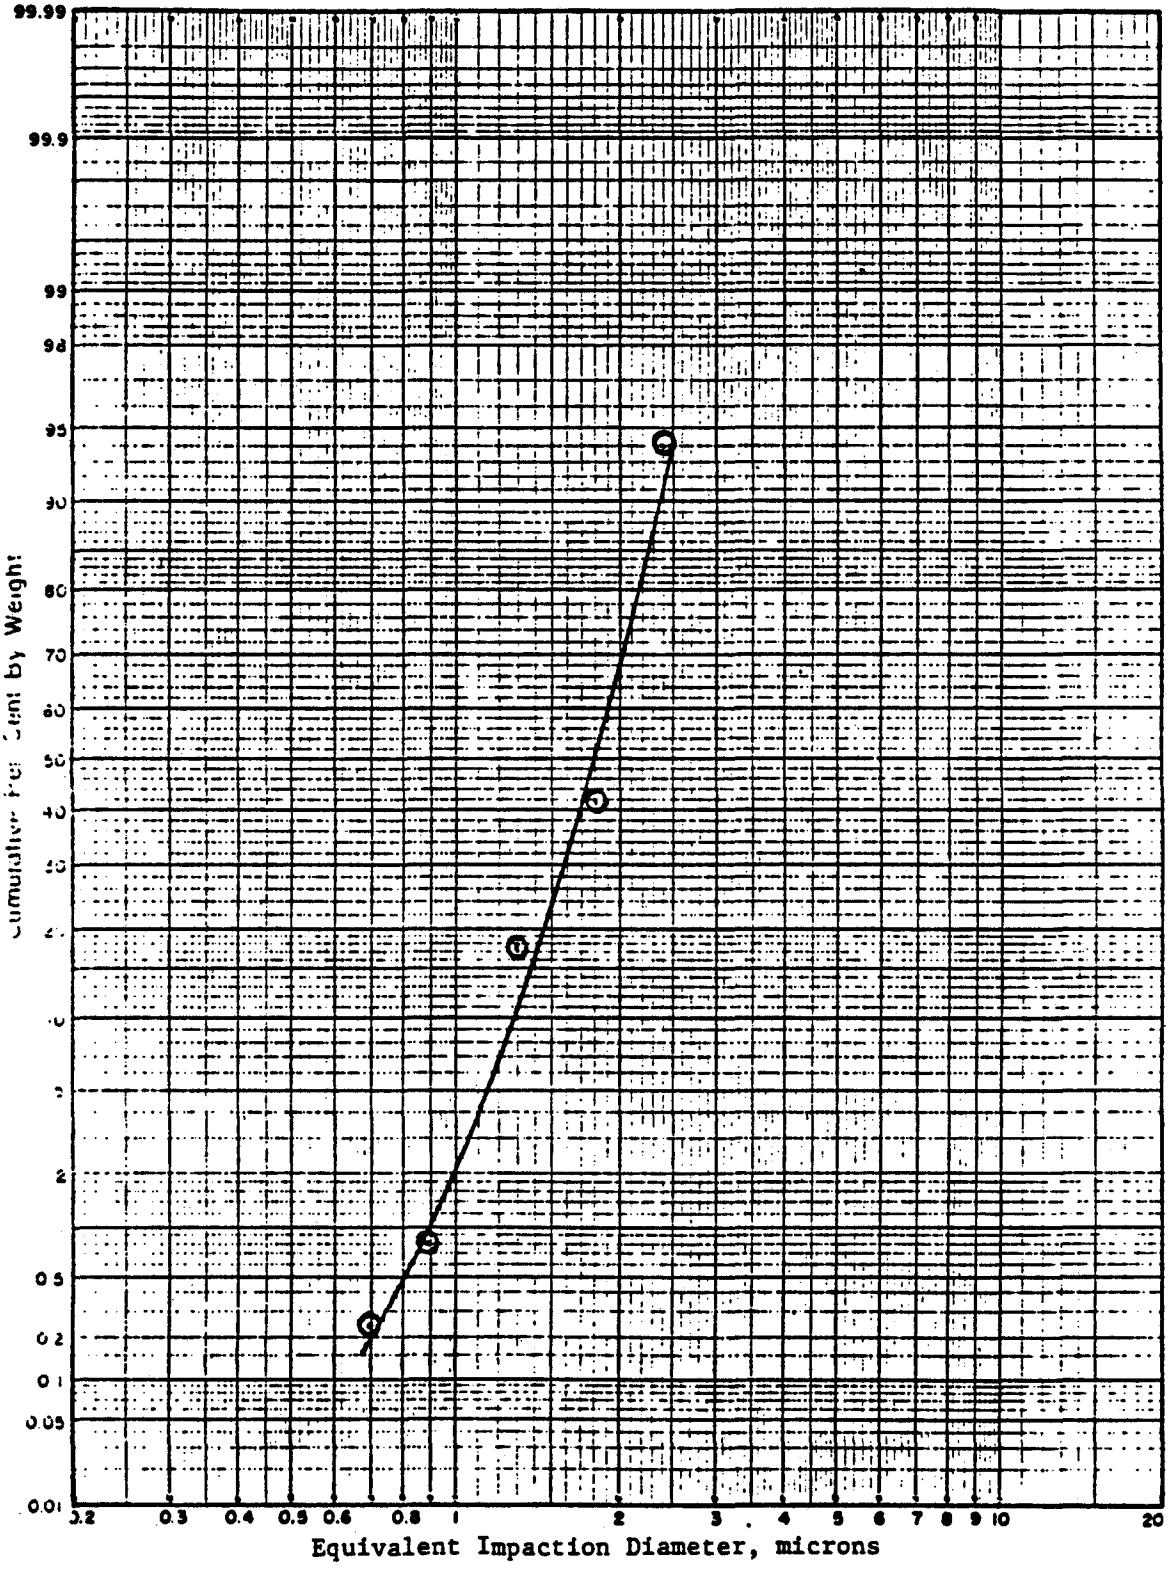

FIGURE 24. IMPACTION EQUIVALENT DIAMETER OF FIBERS COLLECTED ON FILTER FROM CHAMBER 4.

A similar technique was used to characterize the fiber distribution obtained from a Chamber 3 filter. Figure 25 is a plot of the resulting equivalent impaction diamter and shows that the mass-median impaction diameter is 5.8 micrometers as compared with 5.3 micrometers obtained with a cascade impactor (Figure 22). The fibers coated with a phenolic binding (Chambers 1 and 2) failed to correlate with the cascade impactor data. It is believed that the larger charged fibers failed to reach the impaction stages of the cascade impactor. This effect was also noted with the uncoated fibers on several occasions as the impactor size distribution could be vastly different within the same fiber batch.

Uniformity of the fiber concentration in Chamber 2 was also examined with a Sinclair Phoenix aerosol and smoke Photometer.* The photometer measurements were made by sampling along the side of the chamber at the level of the upper and middle animal cages. The photometer was used to monitor stability of the concentration only: the output is not linear and considerable work would be required to calibrate the unit for each of the different types of glass fibers. The photometer measurements in Chamber 2 showed the water droplets produced during the atomizing periods and the subsequent evaporation of the water droplets before the next atomizing period. The photometer measurements also confirmed that the fiber concentrations were equivalent on both sides of the chamber and that the concentrations did not vary significantly during monitoring periods up to about 60 minutes.

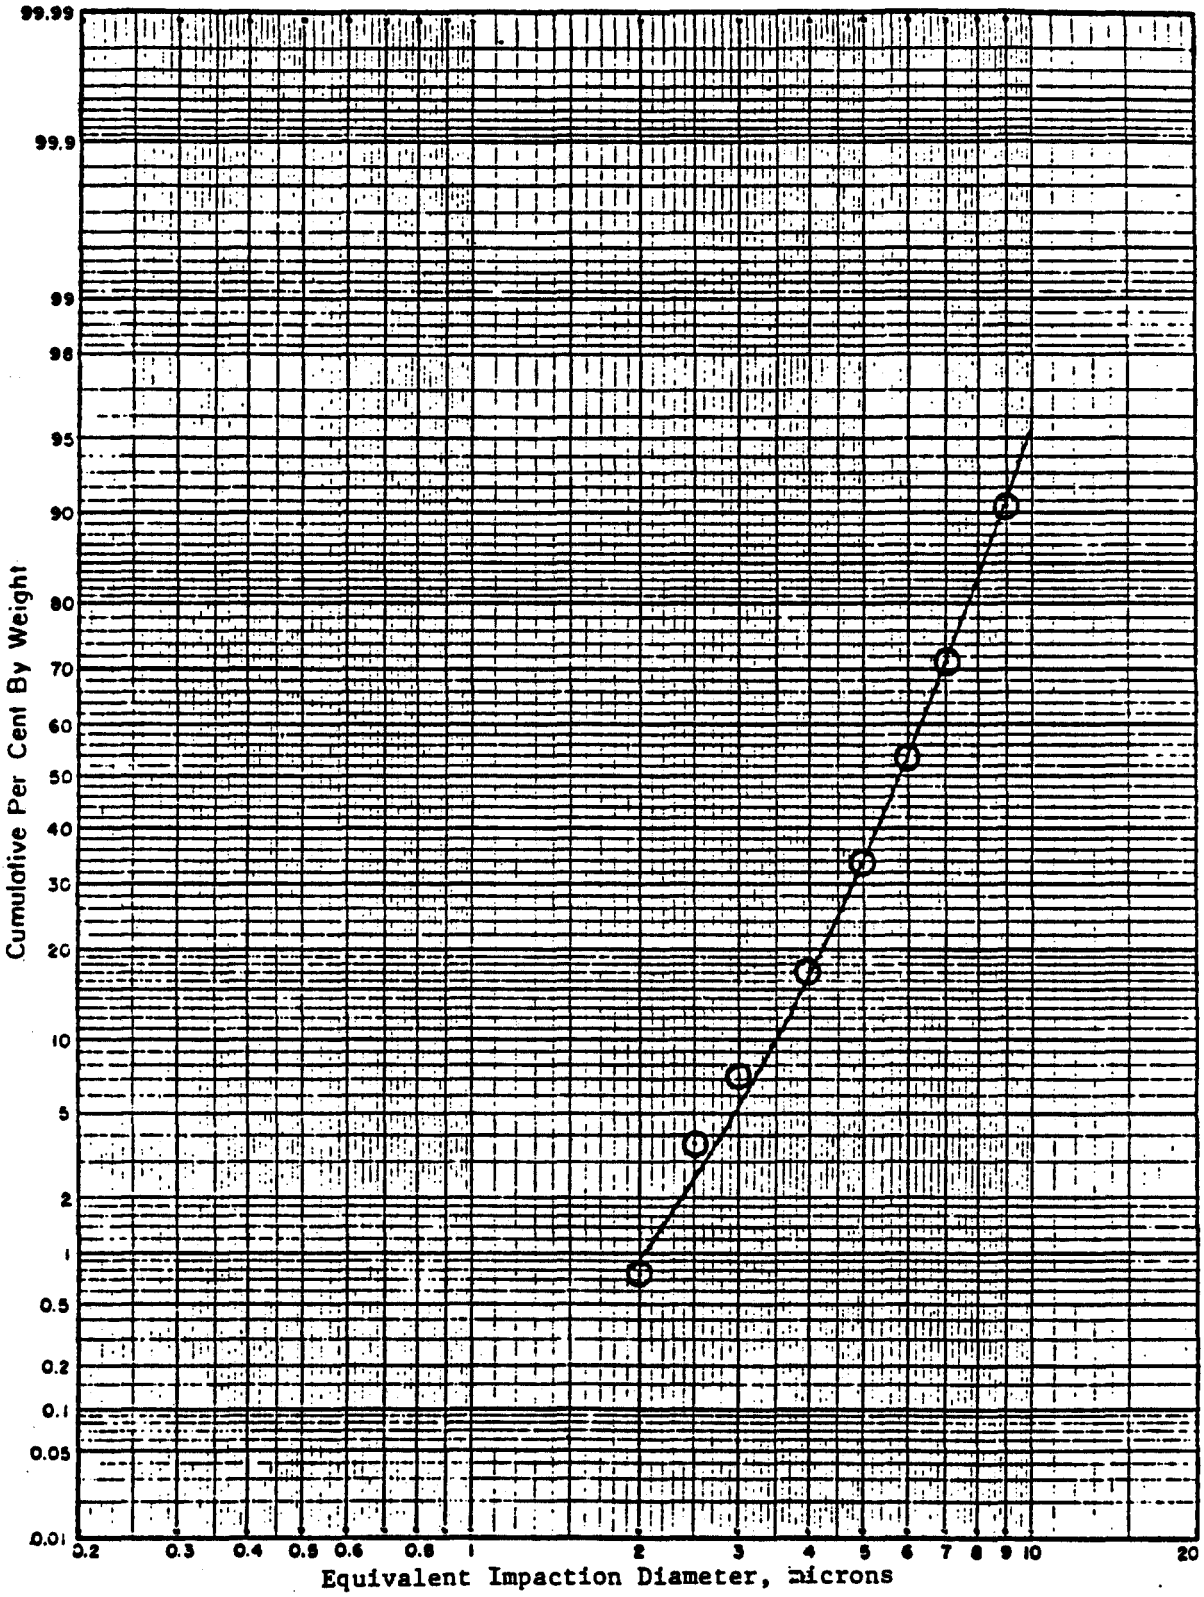

FIGURE 25. IMPACTION EQUIVALENT DIAMETER OF FIBERS COLLECTED ON FILTER FROM CHAMBER 3.

EXPOSURE ENVIRONMENTAL PROCEDURES

Method of Exposure

The animals were exposed for 7 hours per day, 5 days per week, for periods of 72 weeks (monkeys) and 86 weeks (rats), excluding holidays, in Hinners'[33] type chambers which were designed for the health effects research programs conducted at the National Center for Air Pollution Control and the Environmental Protection Agency. These chambers are constructed of stainless steel and are 6 feet square designed with a pyramidal top and bottom with a nominal volume of 5.4 m^3. The doors of the chambers are made of 3/8-inch thick plate glass set in a stainless steel frame and sealed with a neoprene seal. The doors occupy 60 percent of the front side and are held closed with pressure clamps. There are four equally spaced sampling ports in vertical array on each side of the door.

For this study, chambers similar to those shown in Figure 26 were modified to accommodate both rats and monkeys. The interior of the chamber was cleaned daily after each animal exposure with a waterwash ring with high pressure nozzles.

Air was drawn through the chamber by a large blower mounted on the roof of the facility. The air entering each chamber was room air that had been filtered with an absolute filter mounted on the intake to each chamber. The room air had previously been cleaned by an electrostatic precipitator and a bacteriostatic LiCl solution and conditioned to an average 68.8°F and an average 50 percent relative humidity.

At the beginning of the study, a check was made to determine the uniformity of the test-gas concentrations in the Hinners' type exposure chambers. Because a test gas was introduced via the air input metering orifice, it was assumed that its concentrations would be uniform throughout the chamber. This assumption was verified by using methyl chloride as the test gas and monitoring the chamber concentration with an infrared spectrophotometer (MIRAN 1A). A chamber concentration of approximately 400 ppm was used which produced an absorbance reading of 0.39. The chamber was sampled at three levels 12, 24, and 36 inches above the chamber floor. Each level was sampled at 9 points

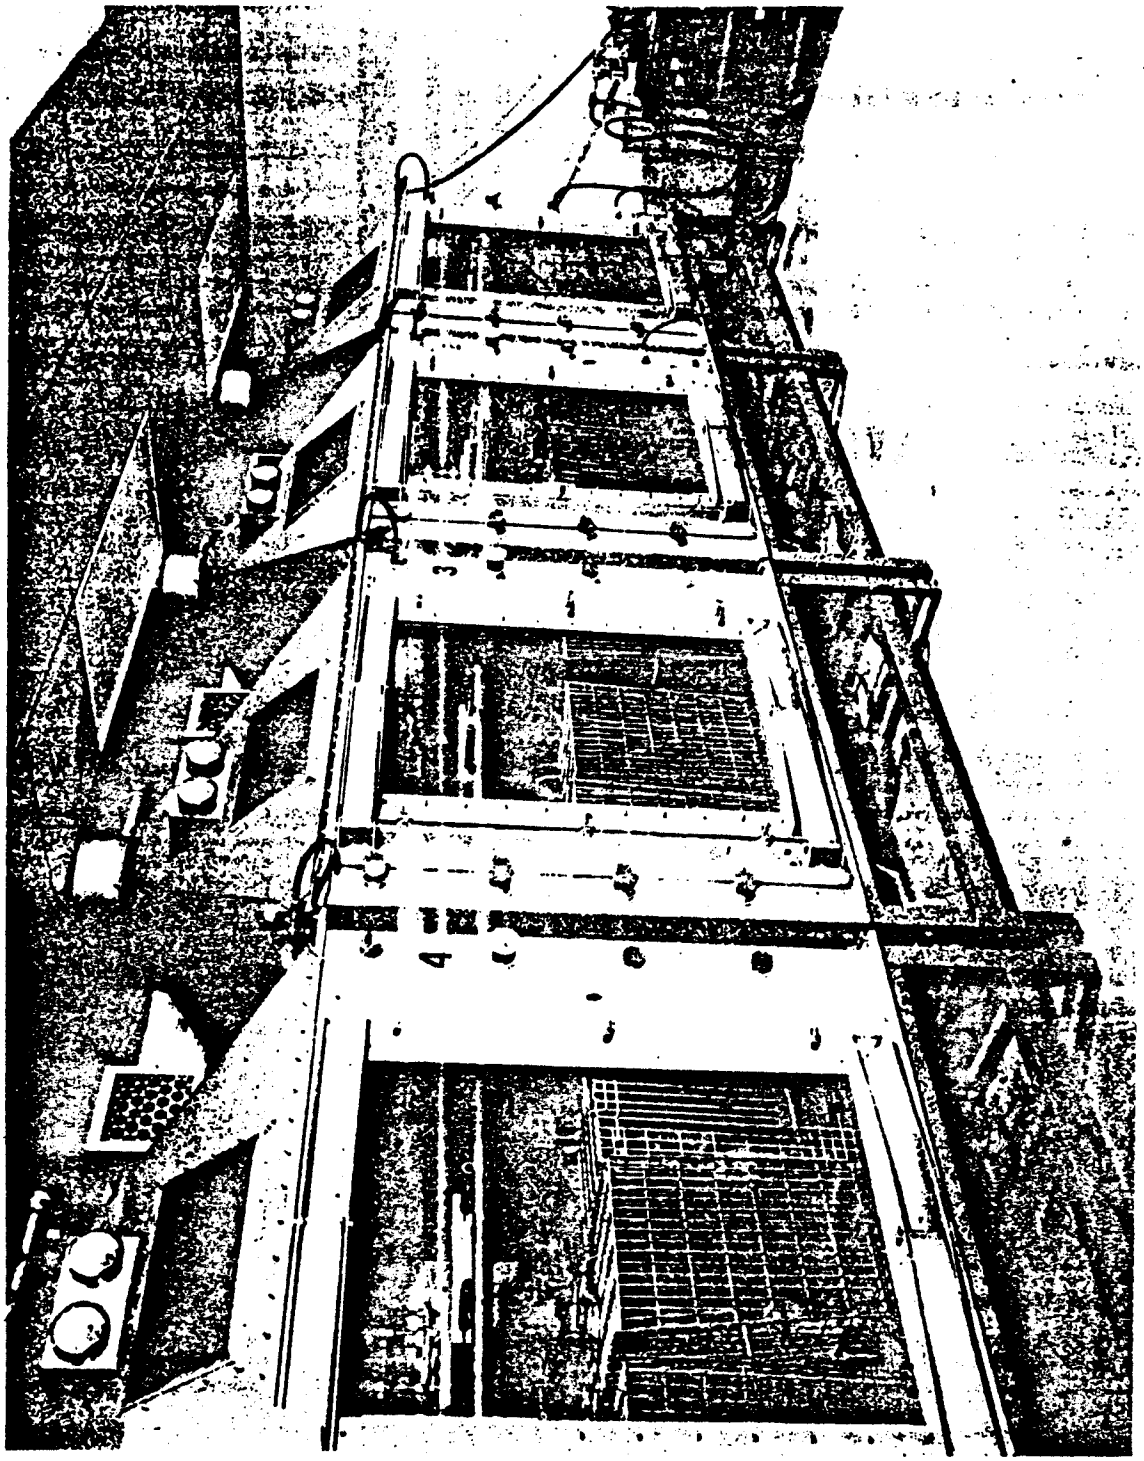

FIGURE 26. PHOTOGRAPH OF ANIMAL INHALATION CHAMBERS

(a 3 x 3 matrix) taken at the front, middle, and back of the chamber at each side at the midline. A total of 27 points was sampled (a 3 x 3 x 3 matrix) and the absorbance reading (0.39) was identical for all points.

To assure randomization of exposure, all cages were rotated from top to bottom and left to right by one position each new exposure day.

Chamber Air Monitoring

The air flow in the exposure chambers was monitored by measuring the pressure drop across an orifice placed in the air inlet as shown in Figure 27.

This orifice was calibrated by means of an ASME Orifice and the theoretical pressure drop across the orifice was calculated. Based upon a flow rate of 1 m^3/min or 35.3 cfm the theoretical change in pressure across the orifice should be 0.19 inches of water. Figure 28 shows the calibration curve obtained.

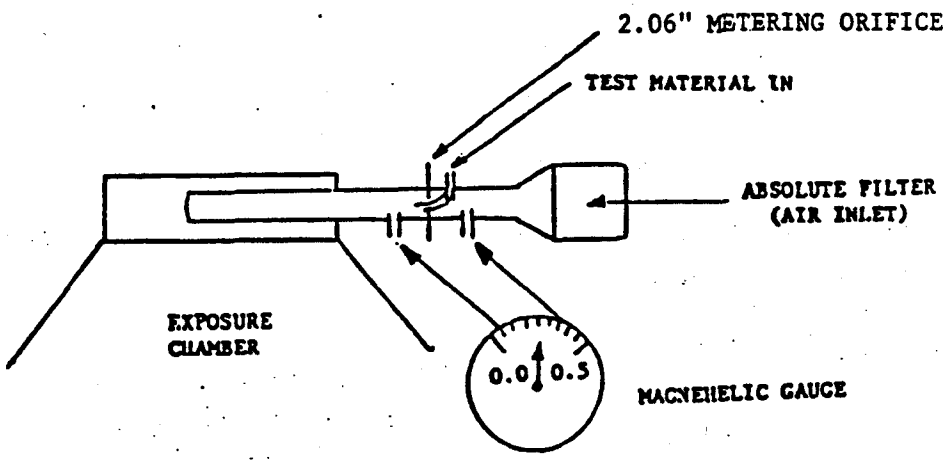

FIGURE 27. SCHEMATIC OF AIR MONITORING SYSTEM

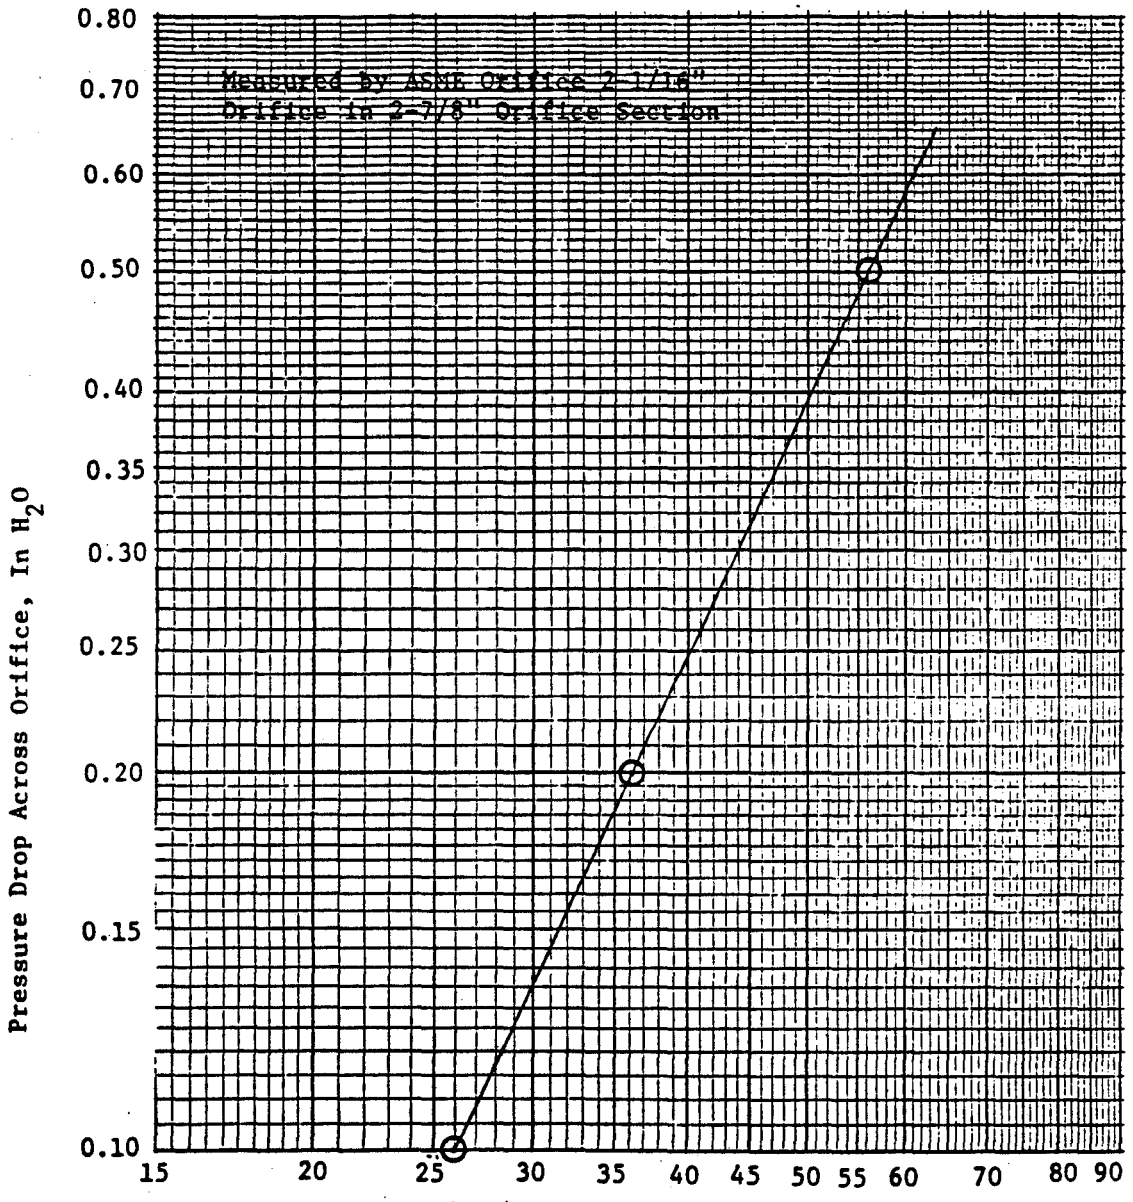

FIGURE 28. CHAMBER AIR FLOW CALIBRATION

RESULTS

EXPOSURE ENVIRONMENT RESULTS

Temperature and Relative Humidity

Throughout this study, only slight variations of relative humidity or temperature were detected for the inhalation chambers. Actual readings varied somewhat, but in accordance with the room environment. The exposure and holding rooms were monitored to determine changes from the desired temperature of 70 $\pm$ 2°F and the desired relative humidity of 45 $\pm$ 5 percent. These measurements were originally made with separate temperature and hygrometer instruments, mounted in each chamber. As the study progressed, the instruments in the interior of the various chambers did not always agree exactly due to a build up of glass fibers on the hygrometer element. The average temperature throughout the study was 68.8 $\pm$ 1.9°F and the relative humidity 50.0 $\pm$ 6.4 percent. The actual records are maintained by the Battelle Quality Assurance Unit of the Biological Sciences Department.

Ammonia Level

During the exposure period, a test was made to determine the ammonia level within a chamber that was fully loaded with test animals. The measurement, which was taken at the end of an exposure period, showed that the ammonia level was approximately 0.2 ppm.

Size Characteristics of Glass Fibers

Besides the measurement of the fiber glass clouds with a cascade impactor (which was previously discussed), samples were collected on absolute filters and subsequent particle size measurements made of photo micrographs taken of these collections.

Figures 29 - 32 are scanning electron micrographs of filters used to obtain mass concentration of the powder cloud in the four chambers. Tables 19 - 22 summarize the particle size measurements of 200 fibers made from these and similar micrographs. Figures 33 - 36 are three-dimensional plots of these data. These figures indicate that the mass of the fibers was within the given specifications.

Filter samples were also given to Dr. Lloyd Stetler (NIOSH-Cincinnati) for particle size analysis. The filter samples were ashed at 100 watts for two hours in a low temperature asher. The residue from each filter was then added to 200 ml of filtered, deionized water. Five drops of Aerosol OT were added to each suspension which was then allowed to stand for 10 minutes. The suspensions were then stirred magnetically for 2 minutes and filtered through a 25 mm diameter, 0.1 μm pore size Nuclepore filter. The filters were mounted on carbon planchets with colloidal graphite and then analyzed in the SEM using a LeMart Scientific Model B-10 image analysis system. Analyses were performed at a magnification of 1000X.

Tables J-1 through J-4 summarize the particle size measurements which were obtained for fibers with aspect ratios of 5:1 and greater. Figures J-1 through J-4 are three-dimensional plots of these data. The results obtained with the automatic counter agree quite well with the manual measurements.

Exposure Concentrations

The protocol specifies that concentration measurements should be made twice a day. However, because of the potentially large variations in concentrations, an attempt was made to make at least four measurements when operational time permitted. Table 23 summarizes the concentrations for the initial time period in which only rats were exposed and the following six quarters in which both rats and monkeys were exposed. In addition, the table shows the overall exposure concentrations for both rats and monkeys. Appendix D shows the average daily chamber concentration.

EXPERIMENTAL ANIMAL RESULTS

Ophthalmic Examination Results

The pretest ophthalmic examinations were performed on monkeys number CM801A through CM816A, CM825A through CM831A and CM867A on February 22, 1979, and on monkeys number CM817A through CM820A, CM822A through CM824A, CM832A through CM846A, CM849A through CM858A, CM860A through CM866A and CM868A on February 23, 1979. At the time of the pretest examination, monkey number CM809A from the F01 group was noted to have lost some of its right eyelid allowing an excessive amount of palpebral conjunctiva to be exposed, and monkey CM829A had a scratch spanning the width of the cornea (top to bottom) with a resultant corneal opacity. No other ocular abnormalities were noted at the pretest eye examination.

The postexposure eye examinations for the F01 group were done on January 15, 1981 (CM839A, CM851A, and CM823A), and January 16, 1981 (CM809A, CM802A, CM865A, CM849A, CM856A, CM843A, CM855A, CM817A and CM858A); the F02 group on January 20, 1981 (CM846A, CM862A, CM864A, and CM834A), January 21, 1981 (CM810A, CM838A, CM840A and CM837A), and January 22, 1981 (CM854A, CM808A and CM813A); the F03 group on January 9, 1981 (CM850A, CM803A, and CM822A), January 12, 1981 (CM835A, CM815A, CM824A, and CM814A) and January 14, 1981 (CM836A, CM833A, CM841A, and CM825A); the F04 group on December 30, 1980 (CM801A and CM807A), December 31, 1980 (CM818A, CM828A, CM812A, CM867A and CM857A), and January 5, 1981 (CM819A, CM830A, CM831A, CM842A and CM832A); and the F05 group postexposure eye examinations were done on December 22, 1980 (CM820A, CM844A, CM805A, CM868A and CM861A) and December 23, 1980 (CM845A, CM860A, CM816A, CM806A, CM829A, CM852A, and CM853A). Postexposure eye examinations were not done on monkey CM811A from the F02 group nor monkey CM863A from the F03 group as both of these animals died before study termination. The only ocular abnormality noted in the monkeys at the postexposure examination was an opaque corneal scar spanning the cornea (top to bottom) on monkey number CM829A where the scratch and scar had previously been. No lesions attributable to fiber exposure were seen in the monkeys.

Discussion of Clinical Observations

With the exceptions of monkey number CM811A who died early with a syndrome analagous to diabetes mellitus (see pathology discussion for details) and monkey number CM863A who was sacrificed in a moribund condition of undetermined cause (also see pathology discussion for details), the monkeys remained in good health throughout the study. Clinical abnormalities noted by the observing technicians were largely minor problems commonly seen in caged primates or problems that resulted from the handling procedures necessary for this study. None of the clinical abnormalities observed in the monkeys was considered to be the result of exposure to the fibrous glass test material.

Some clinical abnormalities were observed commonly in the monkeys, i.e., traumatic lesions, hairloss, nasal discharge or dried exudate in a nostril, varying periods of reduced appetite, and pigmentary alterations. Other abnormalities, such as coughing, wheezing, lumps, and distended abdomens occurred less often. Some abnormalities such as diarrhea, blood in stool, vomiting, and cloudy urine did occur but were very rare.

Traumatic lesions were by far the most commonly noted clinical abnormalities. These lesions included lacerations sustained from a bite from a neighboring monkey (they were in close proximity when in the exposure chambers); lacerations caused by having a finger, toe or tail pinched in the cage when moving from holding room to chamber or vice versa; traumatic lesions that occurred when the monkeys were caught for blood collection and TB testing; or the actual handling and procedures of blood collection and TB testing. Virtually every monkey in the study had a traumatic lesion at some time. Most were very minor, but some did require sutures and monkey number CM832A from the F04 group fractured the radius and ulna of its left arm when an animal technician tried to remove it from its cage.

Another very commonly occurring clinical abnormality in these monkeys was hairloss. It is not uncommon for caged primates to entertain themselves by plucking hair from their body. These monkeys engaged in this pastime frequently. Ten of twelve monkeys in the F01 group, ten of twelve

in F02, eight of twelve in F03, eleven of twelve in F04, and ten of twelve in F05 manifested some hairloss during the months of the study.

Sneezing, nasal discharge, and dried exudate in the nostrils, when considered as a class of clinical observations, occurred in eight of twelve monkeys in F01, ten of twelve in F02, eleven of twelve in F03, nine of twelve in F04, and eight of twelve in F05. This did not progress to anything more profound, nor did it have any apparent effect on the overall condition of the monkeys. The condition occurred in all treatments and the control group with similar frequency. Thus, no significance was attributed to these observations.

Sixty-five percent of the monkeys in this study manifested a reduction in their appetites for some brief period or periods of time. This was true of the monkeys in all groups and occurred at various times during the study period. Such behavior is not uncommon for caged primates, and no particular significance was attached to it.

Thirty-five percent of the monkeys, representing all five groups, had some sort of pigmentary change during the course of the study. These changed ranged from red spots on the face to blue areas on the abdomen to brown spots on the forehead. Many of these pigmentary changes occurred following the healing of a traumatic lesion. As with the other observed abnormalities, they were considered inconsequential.

Besides these commonly observed abnormalities, a number of clinical abnormalities were noted sporadically in these animals with no apparent group or time correlation. Nine of the monkeys had a rough haircoat for some part of the study period, fourteen developed a lump or a cyst (most of these were small swellings that were located beside the nose and were caused by a chronic infection of the canine tooth root), ten monkeys vomited on at least one occasion during study (most of these were in close association with administration of anesthesia for pulmonary function testing), five had a bout of diarrhea, eight had a distended abdomen (soon after eating), and nine had at least one occasion of no stool at all. In addition, nine of the monkeys had periods of coughing and/or wheezing shortly after pulmonary function testing, although this condition was transient. A few other observations were noted sporadically (five ocular discharge, two swollen eyes, five

rashes, two slightly dehydrated and one cloudy urine), but none of these lesions was of any consequence. Seven of the monkeys were observed to be thin and/or weak during the study. Two of these seven were CM811A and CM863A, the two early death animals. The other five completed the study and were considered to be naturally thin animals.

When all of the observed clinical abnormalities are considered, there was nothing seen in the monkeys that could be attributed to fiber exposure and, in fact, most of the observed abnormalities were commonly associated with caged primates. The fact that the protocol requirements of this study necessitated frequent moving and handling of the animals led to greatly increased opportunity for trauma and stress manifestations.

As was the case with the monkeys, the rats did not manifest any clinical signs that could be attributed to exposure to the fibrous glass test material. There were some clinical abnormalities that occurred commonly in the rats of all test groups and the control group. The signs and lesions associated with chronic respiratory disease, such as porphyrin pigmented nasal and ocular discharge and a small area of hairloss with exposed skin at the canthus of both eyes, were seen in most of the animals in every exposure group at some time during the study. The incidence of nasal and/or ocular discharge ranged from 80 to 85 percent among the groups (treatment and control) and the incidence of hairloss at the canthus ranged from 51 to 61 percent. The duration of these signs was from 2 to 3 days to 3 or 3 months.

Another commonly observed clinical abnormality was trauma. Such things as bruised tails, cuts and abrasions of the tail, and cuts on the feet that were caused by being accidentally caught in the cage door occurred in animals from all exposure groups. In the F01 group 24 percent of the animals, 19 percent in F02, 21 percent in F03, 14 percent in F04, and 22 percent in F05 had some sort of traumatic lesion at some time during the study. These lesions generally healed unenventfully and had no apparent impact on the study conclusions.

Late in the study the rats began to have a higher incidence of tumors (commonly in the abdomen and usually the spleen). Incidences ranged from 29 to 40 percent. The occurrence was evenly spread across exposure

groups and controls and was about what would be expected of aging Fischer 344 rats as a result of the Fischer rat leukemia syndrome. Another clinical abnormality that is coincidental with this syndrome and was commonly observed was general paleness. Paleness was observed in 8 to 14 percent of the animals across the exposure groups and controls.

Other commonly occurring clinical abnormalities were eye lesions (i.e. cataract and/or cloudy cornea) in 7 to 14 percent within the exposure and control groups, rough haircoat in 5 to 26 percent from group to group, some alopecia (2 to 14 percent), and some thinness or loss of body condition (4 to 14 percent).

In addition, other abnormalities were noted sporadically and with no apparent correlation to exposure level. Such abnormalities as malocclusion, head tilt, prolapsed vagina, dehydrated, yellowish discharge from the urogenital tract, diarrhea, depression, and bloating were occasionally noted.

As with the monkeys, none of the observed clinical abnormalities were considered to be associated with fiber exposure. Most of the abnormalities are associated with long term confinement of aging rats. The necessity for frequent handling of the rats contributed to the incidence of trauma and other stress-related conditions.

Hematology and Clinical Chemistry

Monkeys

Table 24 shows group means and standard deviations for each group. The baseline mean is the average of two baseline values for each parameter. Results for individual animals are shown in Tables 25 through 29.

There were no changes in mean values for hematology or clinical chemistry parameters that were outside the expected range nor were there any biologically significant variations from control values. There were occasional fluctuations in individual values for a given parameter which is expected but there was no evidence that such changes were related to fiberglass exposure.

There were several changes in the two animals that died spontaneously (i.e., 811A, F02, and 863A, F03). Both monkeys were mildly anemic. Monkey 811A had a mild regenerative anemia at baseline as judged by erythrocyte parameters and reticulocytes. In addition, the BUN was slightly elevated and the IP markedly reduced. No cause of death was determined for monkey 811A. Amyloidosis of pancreatic islets was observed in monkey 863A, was associated with a severe elevation in serum glucose, and was the apparent cause of death. Cholesterol and LDH were mildly elevated in this animal and sodium was mildly depressed.

Rats

Tables 30 and 31 show group means and standard deviations for each group. There were no changes in mean values for any exposure group that indicated an effect resulting from fiberglass exposure. There were occasional mild aberrations, for example, those that occurred in erythrocyte parameters in males from Group F04. The decreases noted resulted from moderately depressed values in two rats in which mononuclear cell leukemia occurred with attendant bone marrow suppression. Mean values were

essentially all within expected limits and comparable to those of control rats, although there were moderate individual variations in most parameters as is normally expected in rats of this age. Such variations in erythrocyte parameters were most prominent in rats with mononuclear cell leukemia, a common finding in aging Fischer 344 rats.

Body Weight and Growth

All rats and monkeys were weighed on a weekly basis for the first month of this chronic study and monthly thereafter. The monkeys were weighed in their cages and the rats were weighed on a digital balance using an automatic capture and recording system. Body weight determinations for dose groups F01 and F03 (April 1980) and F05 (November 1979 and January 1980) were misplaced and are not included.

Three time intervals were selected to statistically compare the body weight data between does groups. There were no significant effects upon body weight from exposure of the rats or monkeys to any of the levles of fiber during the course of the experiment. The following sections are summaries of the statistical observations about each time period and each exposure category.

Monkeys

Table G-1 contains the summary analyses performed on the monkey body weight data. All individual body weight data are tabulated by dose group in Tables G-2 through G-6. The body weight data are presented in Figure 37.

Results of 0-, 9-, and 18-month monkey body weight comparisons. Overall comparisons of the body weight of the monkeys in each dose group showed no significant differences at 0, 9, and 18 months.

Results of 0-18, 0-9, and 9-18 percent weight gain comparisons in monkeys. Overall comparisons of animals dosed in these groups showed no significant differences over the entire 18-month period. Similarly, over the second 9-month period, no statistically significant dose effects were present. The analysis for the first 9 months, however, showed significant differences. Specific inter-group comparisons performed using a two-tailed Dunnett's test revealed that no individual treatment was significantly different from the control. In this case, the mean of F01 group (high dose, wide binder) indicated that group gained weight, while the other four groups had means that indicated animals had lost weight. Thus, F01 group showed a significantly different percent gain, as contrasted with the other four groups, which included the control (F05 group), but no significant differences from the

control were detected comparing each group indivídually. This was probably due to the large error term.

Male Rats

Table G-7 contains the summary analyses performed on the male rat body weight data. All individual body weight data are tabulated by dose group in Tables G-8 through G-12. The body weight data are presented in Figure 38.

Results of 0-, 9-, and 21-month male rat body weight comparisons. Overall comparisons of the animals in these dose groups showed no significant differences in body weights at 0, 9, or 21 months.

Results of 0-21, 0-9, and 9-18 percent weight gain comparisons in male rats. Comparisons over all three periods showed no significant dose effects.

Female Rats

Table G-13 contains the summary analyses performed on the female rat body weight data. All individual body weight data are tabulated by dose group in Tables G-14 through G-18. Figure 39 represents the body weight data.

Results of 0, 9, and 21 month female rat body weight comparisons. At month 0, differences significant at the .05 level were noticed among average ranks of the dose groups, as computed by the Kruskal-Wallis nonparametric analysis of variance (ANOVA). This significance was not noted by the parametric ANOVA's due to outlying initial weights which decreased the value of the F statistic. Dunn's test was used for inter-group comparisons, revealing that group 2 (15 mg/m^3, yellow binder) ranked significantly higher than the control. At month 9, an analysis of variance revealed overall significance, but the Dunnett's test revealed no significant treatments as compared with control. In this case, the control mean was neither the highest nor the lowest group mean, so the other groups did not show significant departures. No dose effect was statistically significant at 21 months.

Results of 0-21, 0-9, and 9-21 percent weight gain comparisons in female rats. The only interval in which there were significant differences in weight change among the treatment groups was that of the first 9 months. In that interval, the Dunn's inter-group comparisons revealed that the control group ranked significantly higher than F02 group. This indicates that F02 group grew more slowly during the first interval than did the control.

Life Table Analysis

Male Rats

Tables H-1 through H-5 are the life table analyses of mortality and Figure 40 is the corresponding cumulative survival plots. In the analysis none of the inter-group comparisons with the control group were significantly different. However, dose groups F02 and F03 were significantly different and groups F03 and F04 also were significantly different, with group F03 having a lower proportion surviving than either group F02 or F04.

Female Rats

Tables H-6 through H-10 are the life table analyses of mortality and Figure 41 is the corresponding cumulative survival plot. In the analysis none of the between group comparisons with the control group were significant. However, dose groups F02 and F03 were significantly different, and groups F03 and F04 also were significantly different, with group F03 having a higher proportion surviving than either group F02 or F04.

Pulmonary Function Results

The results of the pulmonary function evaluation are summarized in Tables 32 through 36. These tables list the means and standard deviations of all pulmonary function parameters that were calculated for this program at each of the three evaluation periods. Each table represents one exposure group. Those parameters dependent on functional residual capacity are not included because FRC measurements were considered to be unacceptable due to N_2 analyzer malfunction.

The one way analysis of variance (ANOVA) and the Kruskal-Wallis one way rank analysis of variance were used to evaluate the group statistics for the pulmonary data. Bartlett's test was used to validate the ANOVA. Those parameters that demonstrated non-homogeneous variance (Bartlett's $P > 0.05$) were tested by the non-parametric Kruskal-Wallis evaluation. For all procedures, the 95% level of significance was used.

At the 9-month evaluation, several parameters appeared to be different when compared statistically ($P < 0.05$) with controls. Dynamic compliance was higher in the 15 mg/m^3 > 10 μm, 15 mg/m^3 > 20 μm, and the 5 mg/m^3 > 10 μm groups. Volume of anatomical dead space was lower in the 15 mg/m^3 > 20 μm group as well as the 5 mg/m^3 < 20 μm group. Because the nitrogen concentration analyzer did not perform correctly on occasion during the study, little significance is placed upon the measurements of the volume of anatomical dead space.

Of the parameters tested for this study, only expiratory reserve volume (ERV) and forced expiratory volume at 0.5 second normalized to forced vital capacity (FEV.5/FVC) showed significant results ($P < 0.05$) after the 18-month evaluations. ERV was reduced significantly in both the 15 mg/m^3 > 10 μm and 15 mg/m^3 > 20 μm exposure groups but not in either of the 5 mg/m^3 groups. Additionally, the FEV.5/FVC parameter was elevated in the 15 mg/m^3 > 20 μm exposure group when compared to controls. Non-normally distributed parameters did not show significant ($P > 0.05$) difference by Kruskal-Wallis after 18 months of exposure.

1 Physiology Parameter definitions as per Table 1 on page 18 of text.

* Significant difference from control values at the same time period ($P<0.05$)

The limited number of significant differences demonstrated by pulmonary function analysis does not provide a basis for the diagnosis of any pattern of respiratory compromise. As all calculated parameters in both of the 5 mg/m^3 (F03 and F04) exposure groups were not significantly ($P>0.05$) different from the control group, it must be concluded that, within the capabilities of our evaluation, no substantiated changes occurred in those two groups as a result of their exposure to fibrous glass. The reduction of ERV alone, as in the case of the F02 group exposed to 15 mg/m^3 (> 10 μm) fibers or in conjunction with an increased FEV.5/FVC, as in the F01 group exposed to 15 mg/m^3 (> 20 μm) fibers, is not representative of either restrictive or obstructive lung impairment patterns. An indication of altered inflation is suggested by a trend to increased inspiratory capacity and a significant decrease in expiratory reserve volume. Such an indication cannot be clarified, however, because of the malfunction of the N_2 analyzer. In conclusion, no significant or meaningful changes could be attributed to exposure to the fibrous glass as determined by our pulmonary function evaluations in monkeys.

Gross and Microscopic Pathology

Monkeys

Observations recorded during necropsy are shown for individual animals in Tables I-1 through I-5 and are summarized in Table 37. Microscopic lesions are shown for individual animals in Tables I-6 through I-10 and are summarized in Table 38. Lesions involving fibrosis or smooth muscle hyperplasia are summarized in Tables 39 and 40 so the distribution and frequency of these changes among the various dosage groups can be more easily seen.

There were extensive numbers of diagnoses made in examining the lungs of monkeys in this study. Although nearly all of these changes were apparently the result of lung mite infestations, it was considered to be necessary to delineate these lesions, and where applicable, to identify involvement in a specific lobe or lobes. Although this allows more definitive evaluation and separation of the changes, it also results in a somewhat confusing array of summarized lesions.

The only unequivocal microscopic changes that resulted from exposure to fiberglass occurred in the lungs and tracheobronchial lymph nodes of monkeys from all exposure groups. Lesions in the tracheobronchial lymph nodes consisted of minimal to moderate amounts of fiberglass in macrophages usually in the medulla of the lymph node (Figures 42 and 43). Changes in the lungs were generally mild and consisted of single macrophages or small aggregates of macrophages that contained fiberglass fibers (Figures 44, 45, and 46). This was the major fiberglass-induced pulmonary change and was diagnosed as macrophage aggregates with fiberglass deposition. A few free fiberglass fibers were visible in alveoli, interstitium, or other areas in the lungs of monkeys

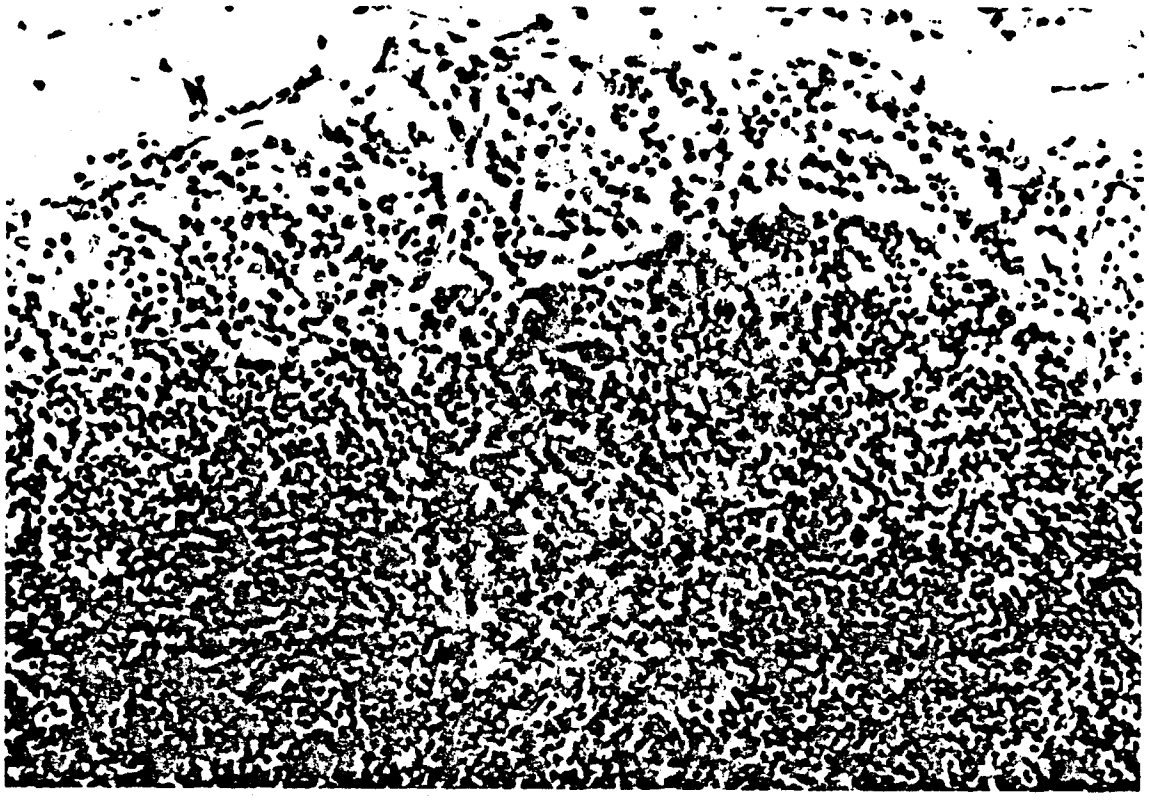

Figure 42. Tracheobronchial lymph node (50X), male monkey, F04 group. A large macrophage aggregate is present in the medulla and contains moderate amounts of fibrous glass and lung mite pigment.

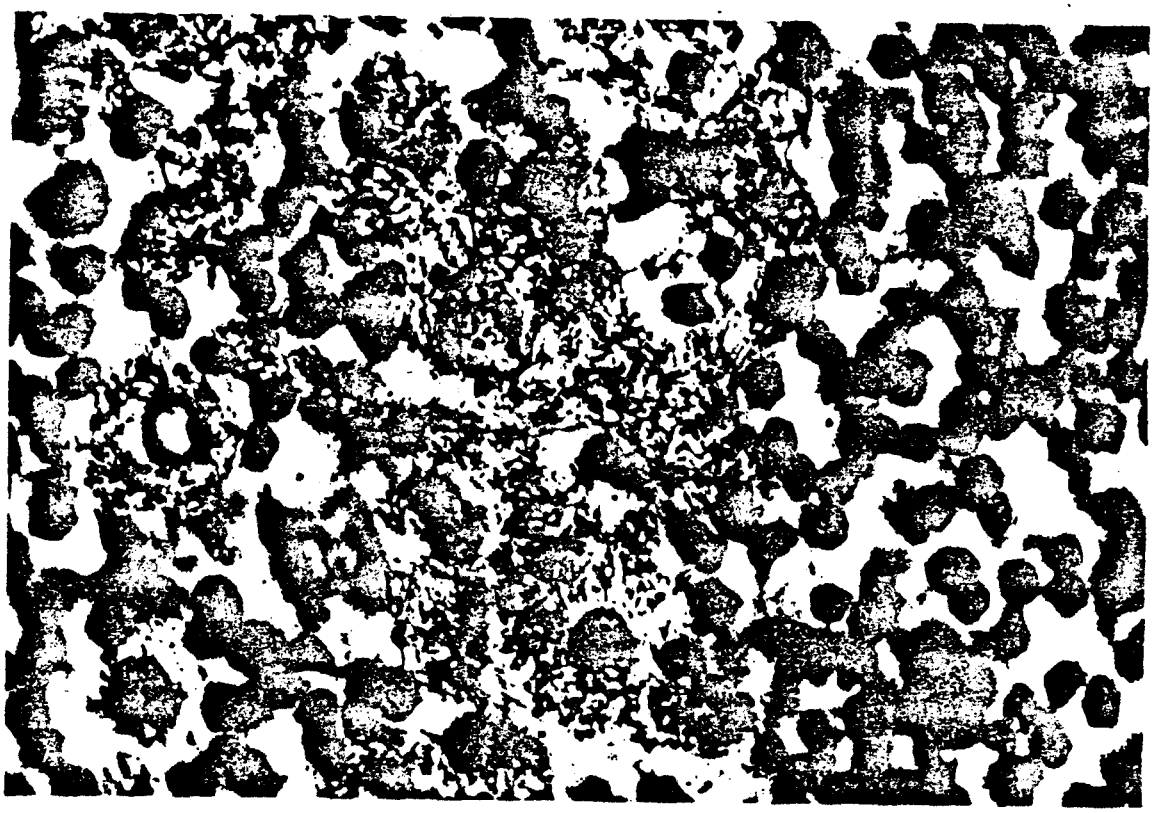

Figure 43. Tracheobronchial lymph node (250X - reduced light), male monkey, F04 group. Fibrous glass particles are clearly depicted in the macrophage aggregate.

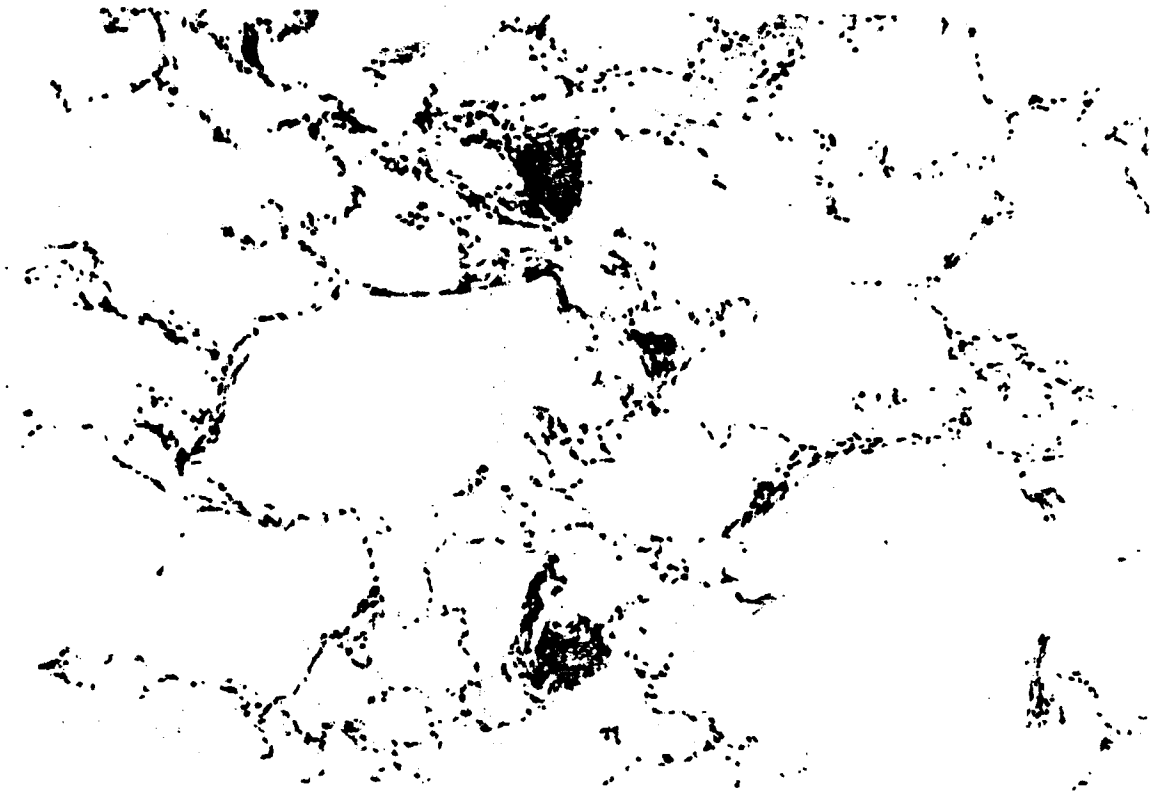

Figure 44. Lung (25X), male monkey, F04 group. Macrophage aggregates are present in the alveoli and about blood vessels which contain fibrous glass and lung mite pigment.

Figure 45. Lung (250X - reduced light), male monkey, F04 group. Fibrous glass particles and lung mite pigment are clearly depicted in this alveolar macrophage aggregate.

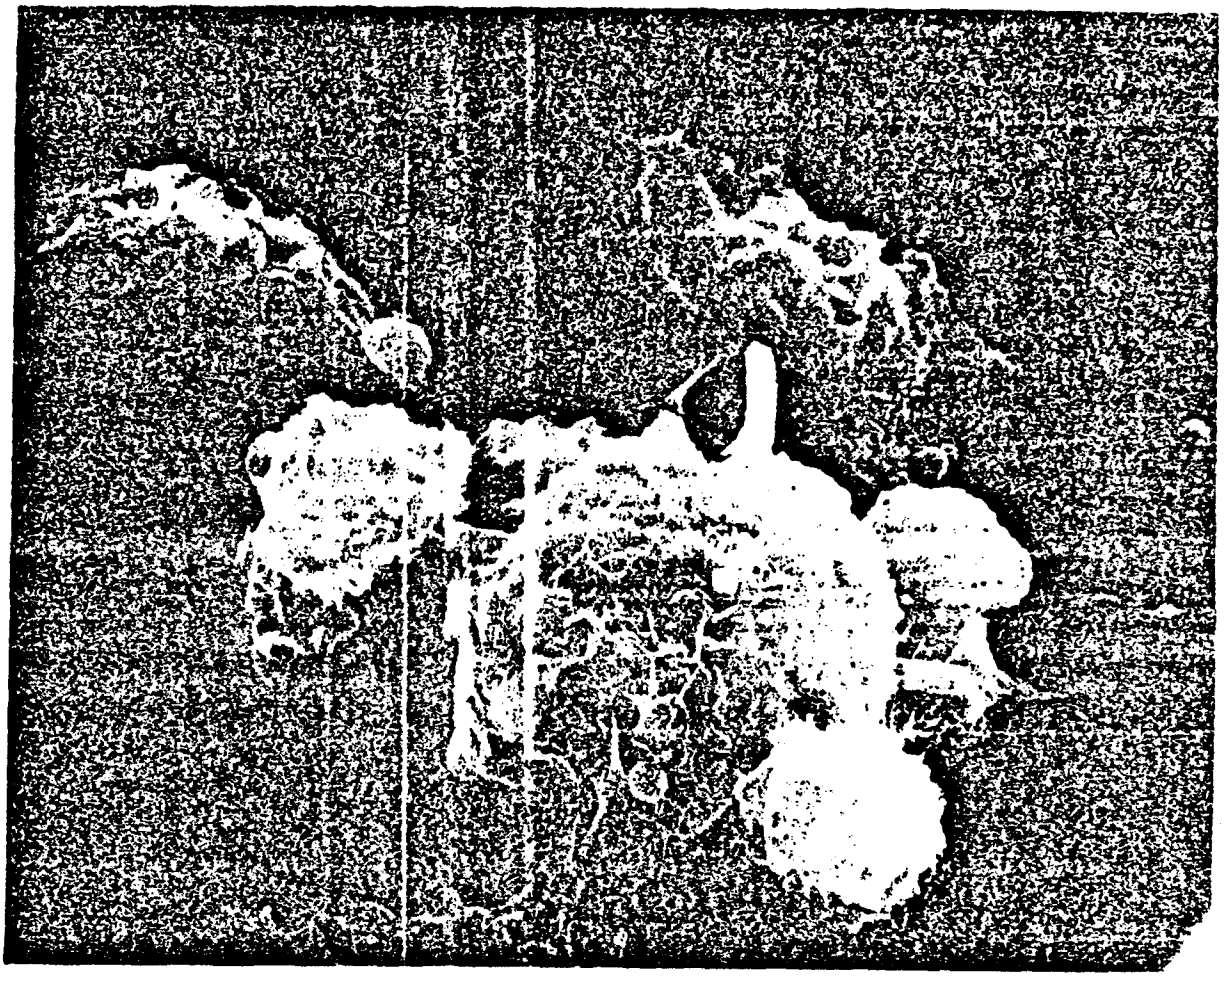

Figure 46. This SEM photograph (2500X) depicts several fibrous glass-laden alveolar macrophages that were obtained by pulmonary gavage from a male monkey (Group F02, Animal #811A) that died spontaneously.

exposed to fiberglass fibers and was included in the above diagnosis rather than being listed as a separate change. Macrophages containing fiberglass were usually located in peribronchiolar, peribronchial, or perivascular areas as well as within alveoli and in pleural and subpleural locations. There were no obvious differences in the lobar distribution of these fiberglass-containing macrophages or free fiberglass fibers. In many instances, the macrophages that contained fiberglass also contained pigment and debris typical of that resulting from infestation with lung mites (Pneumonyssus simicola). Although fiberglass-containing macrophages and free fibers occurred in pleural and subpleural locations and fiberglass-containing macrophages were prominent in tracheobronchial lymph nodes, there was no further evidence of translocation of fiberglass fibers. There was no evidence of fiberglass in organs other than lungs and tracheobronchial lymph nodes.

The only other change that was apparent in fiberglass-exposed monkeys occurred solely in Group F01. This change consisted of mildly increased numbers of lymphoid nodules or aggregates in peribronchiolar and perivascular areas. There were no other associated changes nor did this change occur in other fiberglass-exposed groups or in controls.

There were differences in the extent of involvement among the various exposure groups. This was observed as a substantially less extensive involvement of animals from the F01 group (15 mg/m^3 > 20 micrometer with binder) as compared to the other exposed groups. There were minimal variations in qualitative or quantitative fiberglass-related changes in lungs or tracheobronchial lymph nodes among animals from the other three exposure groups. Numbers and qualitative severities of the fiberglass-induced pulmonary lesion and tracheobronchial lymph node lesion (i.e., macrophage aggregates with fiberglass deposition [lung] and fiberglass deposition [tracheobronchial lymph node]) are as follows:

		Number Involved			
		Group	Group	Group	Group
Lesion	Severity	F01	F02	F03	F04
Pulmonary	Minimal	5	1	-	-
	Mild		10	11	12
	Moderate	1	1	1	-
	No lesion	6	-	-	-

Tracheobronchial lymph node	Minimal	2	5	1	1
	Mild	2	3	6	4
	Moderate	-	2	5	5
	No lesion	7	2	-	2

The only difference was a slightly greater general severity for groups F03 and F04 as compared to Group F02 for the tracheobronchial lymph node lesion. The fiberglass-containing macrophages, in the lungs of virtually all monkeys, occupied less than 5 percent of the total area of the lung sections.

Fifty-nine of the 60 monkeys used in this study had lesions consistent with lung mite infestation. These lesions ranged from the presence of lung mite pigment and debris in macrophages to extensive lesions, including bronchiolitis that was usually eosinophilic and/or granulomatous. Bronchiectasis was present in a few animals and parasites or remnants of parasites were observed in the lungs of some monkeys. Fibrosis and/or smooth muscle hyperplasia was common in the lungs of animals from all groups. These changes were nearly always focal or multifocal and were qualitatively and quantitatively similar among all dosage groups. The smooth muscle hyperplasia, fibrosis, pleural adhesions, and most inflammatory changes in the lungs of these monkeys were apparently related to the lung mite infestations. The distribution of the smooth muscle hyperplasia suggested that it occurred primarily as a result of local changes in ventilatory mechanics. Lung mite pigments and debris usually coexisted with fiberglass in the pulmonary macrophages of monkeys from groups exposed to fiberglass. The numbers of single macrophages and macrophage aggregates were, however, mildly to moderately increased in some animals from each of the exposure groups.

Inflammatory lesions of the nasal passages, trachea, and paranasal sinuses were slightly more prominent in monkeys from Group F04 as compared to controls. However, the diversity of these changes and their mild intensity does not make a definitive interpretation possible.

Other microscopic lesions in these monkeys were apparently unrelated to the fiberglass exposures because they occurred in both control and exposed groups with similar frequency, because they commonly occur in monkeys of this species, or because of the presence of an identifiable etiology such as parasite infestation.

There was no evidence that any of the changes observed at necropsy were associated with exposure to fiberglass. Many of the lesions observed grossly were consistent with parasite infestations. The anthracosilicosis that was described grossly in monkeys from all groups resulted from the black or green-black depositions of lung mite pigments which are common in cynomologous monkeys. Most pulmonary changes that were described grossly were apparently the result of lung mite infestations.

Grossly observed subcapsular splenic nodules are noteworthy although not related to fiberglass exposure. Although the basic changes were similar, the specific characteristics varied so that several different diagnoses were made in different animals. These changes included eosinophilic or neutrophilic infiltrates, reticulum cell hyperplasia, or granulomatous inflammation, all of which were focal or multifocal and occurred in various combinations. Microfilarial parasites were observed in these lesions in several animals and appeared to be the inciting agent.

Two monkeys died spontaneously during the course of the study. One of these monkeys was from Group F02 (811A) and the other was from Group F03 (863A). There was no indication that the deaths of either of these monkeys were related to fiberglass exposure. The cause of death in monkey 811A could not be determined from changes observed grossly, microscopically, or by serum chemistry or hematologic anlaysis. The apparent cause of death in monkey 863A was amyloidosis of pancreatic islets resulting in diabetes mellitus as reflected in the profoundly elevated serum glucose. Other histological changes were observed in this monkey, the most notable being tubular hyperplasia and tubular carcinoma that occurred in the left kidney. There was no evidence that any of these changes resulted from fiberglass exposure.

Early Death Rats

Observations recorded during necropsy are shown for individual animals in Tables I-11 through I-15 and are summarized in Table 41. Microscopic lesions are shown for individual animals in Tables I-16 through I-20 and are summarized in Table 42.

( ) = NUMBER OF ORGANS PRESENT AND ADEQUATE FOR EVALUATION

During the course of this study, 187 rats died spontaneously or were sacrificed in a moribund condition. Many of the spontaneous deaths were due to mononuclear cell leukemia and/or pituitary adenomas, both of which are commonly seen in aged Fischer 344 rats. Other animals were sacrificed because of large skin tumors, such as fibroadenomas of the mammary gland, etc. With the exception of mononuclear cell leukemia, there appears to be no increased incidence of these lesions in the fibrous glass test groups when compared to the control group of animals.

Plaque-like lesions of the pleura were the only lesions observed at necropsy that were attributed to fibrous glass exposure. These plaque-like lesions consisted of gray to tan, elevated, firm areas of various sizes on the surface of the lung lobes. These lesions occurred in 1 of 19 females from the F01 group (15 mg/m^3 > 20 micrometer fiber with binder), in 5 of 23 females from the F02 group (15 mg/m^3 > 10 micrometer fiber with binder), in 2 of 12 females and in 4 of 18 males from the F03 group (5 mg/m^3 > 10 micrometer without binder), and in 5 of 26 females from the F04 group (5 mg/m^3 < 10 micrometer without binder). The superficial lung lesions in the animals from the F04 group were "gritty" or "granular" in character.

There were many additional lesions recorded at necropsy in a variety of organs, all considered to be spontaneous due to their nature, incidence, or severity, or due to a similar incidence between the control group (F05) and those exposed to fibrous glass. Histomorphologic lesions induced by fibrous glass were limited to the lungs, pleura, and lymph nodes (thymic and tracheobronchial) in rats from all exposure groups.

The lung lesions consisted of small to large aggregations of macrophages containing a few to many non-polarizable needle-shaped fibers (fibrous glass), readily seen under reduced light and located in peribronchiolar, peribronchial, or perivascular areas as well as within alveoli and in pleural and subpleural locations.

In many animals, there was granulomatous inflammation of the lung and pleura that was minimal to severe and apparently associated with fibrous glass deposition. This inflammatory response consisted of fibrous glass-laden macrophage aggregates that were surrounded by varying numbers of lymphocytes, plasma cells, and, at times, neutrophils. There were no obvious differences

in the lobar distribution of these pulmonary lesions in the affected rats. The fibrous glass-containing macrophages, in lungs of virtually all rats, occupied less than 5 percent of the total area of the lung sections.

The thymic and tracheobronchial lymph nodes contained various amounts of fibrous glass fibers, usually in the medulla of the lymph node.

Although fibrous glass-laden macrophages occurred in pleural and subpleural locations and were present in thymic and tracheobronchial lymph nodes, there was no evidence of translocation of fibrous glass fibers to other organs in these rats.

There were substantial variations in qualitative and quantitative fibrous glass-related changes among the various exposure groups in the lungs and thymic and tracheobronchial lymph nodes. These changes were least pronounced in the F01 group, became progressively more pronounced in the F02 and F03 groups, and were most pronounced in the F04 group. Table 43 depicts the numbers of animals affected per exposure group and the qualitative severities of the fibrous glass-induced lesions in the lung and lymph nodes (thymic and tracheobronchial).

Four of 20 male rats from the F04 group had mesotheliomas that primarily involved the testis (no other early death animals had this lesion). However, we believe that this neoplastic process was spontaneous because this tumor commonly occurs in aged Fischer 344 rats and there was no evidence of fibrous glass about or within (translocation) the serosal surfaces of the testis.

Many early death rats in this study had mononuclear cell leukemia (Fischer rat leukemia) are depicted in Table 44. The male rats in the F05 (control) group appeared to have a lower incidence of mononuclear cell leukemia when compared to the male and female rats in the other test groups.

There were many additional lesions seen microscopically in a variety of organs, all of which were considered to be spontaneous due to their nature, incidence, or severity, or due to a similar incidence between the control group and those exposed to fibrous glass.

Gross and Microscopic Pathology (Continued)

Scheduled Sacrifice Rats

Observations recorded during necropsy are shown for individual animals in Tables I-21 through I-25 and are summarized in Table 45. Microscopic lesions are shown for individual animals in Tables I-26 through I-30 and are summarized in Table 46.

A total of 313 rats were sacrificed by group, beginning with the F01 group (15 mg/m^3 > 20 micrometer fiber with binder), terminated on April 16, 1981, and ending with the control group (F05), terminated on April 22, 1981. Plaque-like lesions of the pleura were the only lesions observed at necropsy attributed to fibrous glass exposure. Essentially no gross lesions were observed in the respiratory tracts of rats from the control group (F05) or in rats from the F01 group (Figure 47).

Plaque-like lesions of the pleura occurred in 25 of 27 females and in all 31 males from the F02 group (15 mg/m^3 > 10 micrometer fiber with binder). These lesions were multifocal, gray to tan, elevated, firm plaques that measured 1 to 6 or more millimeters in diameter. They were on the surface of the lung lobes and primarily involved the dorsal aspect of the diaphragmatic lobes. In one male rat (Pathology Number 804717), there were extensive fibrous adhesions between the left diaphragmatic lung lobe and both the diaphragm and adjacent thoracic wall.

Plaque-like lesions of the pleura occurred in 34 of 38 females and in 27 of 32 males from the F03 group (5 mg/m^3 > 10 micrometer plain fiber). These pulmonary lesions were similar those seen in the F02 group; however, they were smaller and there were fewer plaque-like lesions per lung lobe (Figure 48).

Plaque-like lesions of the pleura occurred in all 24 females and in 26 of 30 males from the F04 group (5 mg/m^3 < 10 micrometer plain fiber). Thirty-six animals (18 females and 18 males) from this group had superficial lung lesions as previously described; however, the plaque-like lesions were less extensive than those from animals in the F03 group. Most lesions were about 1 millimeter in diameter and there were often only a few plaques per lung lobe. Fourteen animals (6 females and 8 males) from this group had plaque-like lesions that were less than 1 millimeter in diameter and/or a

Figure 47. Lung, male rat, control group. Normal left and right lung lobes.

Figure 48. Lung, female rat, F03 group. All lung lobes have multifocal gray to tan, elevated, firm plagues, measuring 1 to 3 millimeters in diameter.

pleural surface that was "granular" in character. The "granular" lesions of the pleura were about equally distributed in all lung lobes in these animals (Figure 49).

There were many additional lesions recorded at necropsy in a variety of organs, all of which were considered to be spontaneous due to their nature, incidence, or severity, or due to a similar incidence between the control group (F05) and those exposed to fibrous glass.

Fibrous glass-induced histomorphologic lesions were primarily limited to the lungs, pleura, and thymic and tracheobronchial lymph nodes in rats from all exposure groups.

The lung lesions consisted of small to large aggregations of macrophages containing various amounts of nonpolarizable needle-shaped fibers (fibrous glass), readily seen under reduced light, and located in peribronchiolar, peribronchial, or perivascular areas as well as within alveoli and in pleural and subpleural locations. In many animals, there was granulomatous inflammation in the lung and pleura that was of minimal to severe intensity (Figures 50 and 51). This inflammatory response consisted of fibrous glass-laden macrophage aggregates that were surrounded by varying numbers of lymphocytes, plasma cells, and, at times, neutrophils (Figure 52). These pulmonary lesions appeared to be more severe and prevalent in the diaphragmatic areas of the lung lobes in the affected rats. The fibrous glass-containing macrophages, in lungs of virtually all rats, occupied less than 5 percent of the total area of the lung sections.

The thymic and tracheobronchial lymph nodes contained small to large aggregations of macrophages containing various amounts of fibrous glass fibers that were usually in the medulla of the lymph node (Figures 53 and 54). Granulomatous inflammation was present in some sections of lymph node in a few rats exposed to fibrous glass.

Although fibrous glass-laden macrophages occurred in pleural and subpleural locations and were present in thymic and tracheobronchial lymph nodes, there was little evidence of translocation of fibrous glass fibers in other organs in the rats in this study. However, two male rats in the F01 group had a few small macrophage aggregates laden with fibrous glass in their mesenteric lymph nodes.

Figure 49. Lung, female rat, F04 group. The pleura has a "granular" surface involving all the lung lobes.

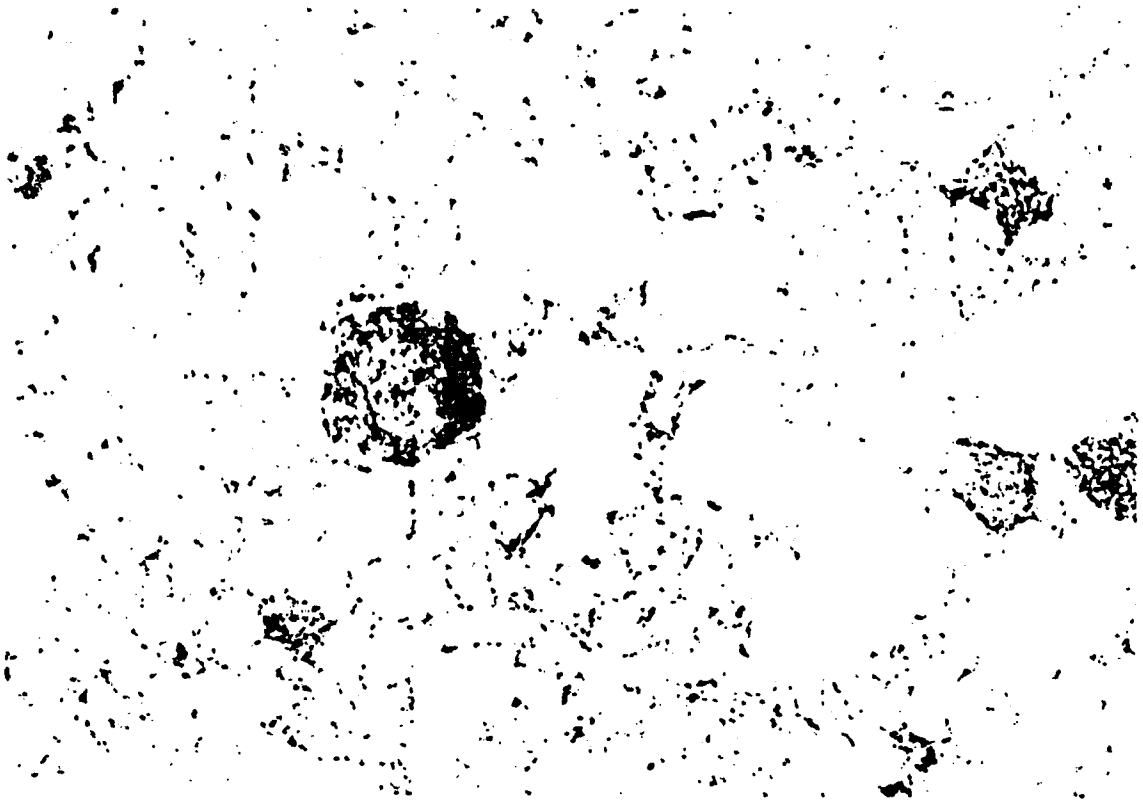

Figure 50. Lung (25X), male rat, F03 group. Many granulomas are present in the alveoli that are mild to moderate in intensity. The macrophages are laden with numerous fibrous glass particles.

Figure 51. Lung - pleura (25X), male rat, F03 group. A granuloma is present in the pleura that is moderate in intensity. The macrophages are laden with many fibrous glass particles.

Figure 52. Lung (100X), male rat, F04 group. The granulomas are characterized by fibrous glass - laden macrophage aggregates which are surrounded by varying numbers of lymphocytes, plasma cells, and, at times, neutrophils.

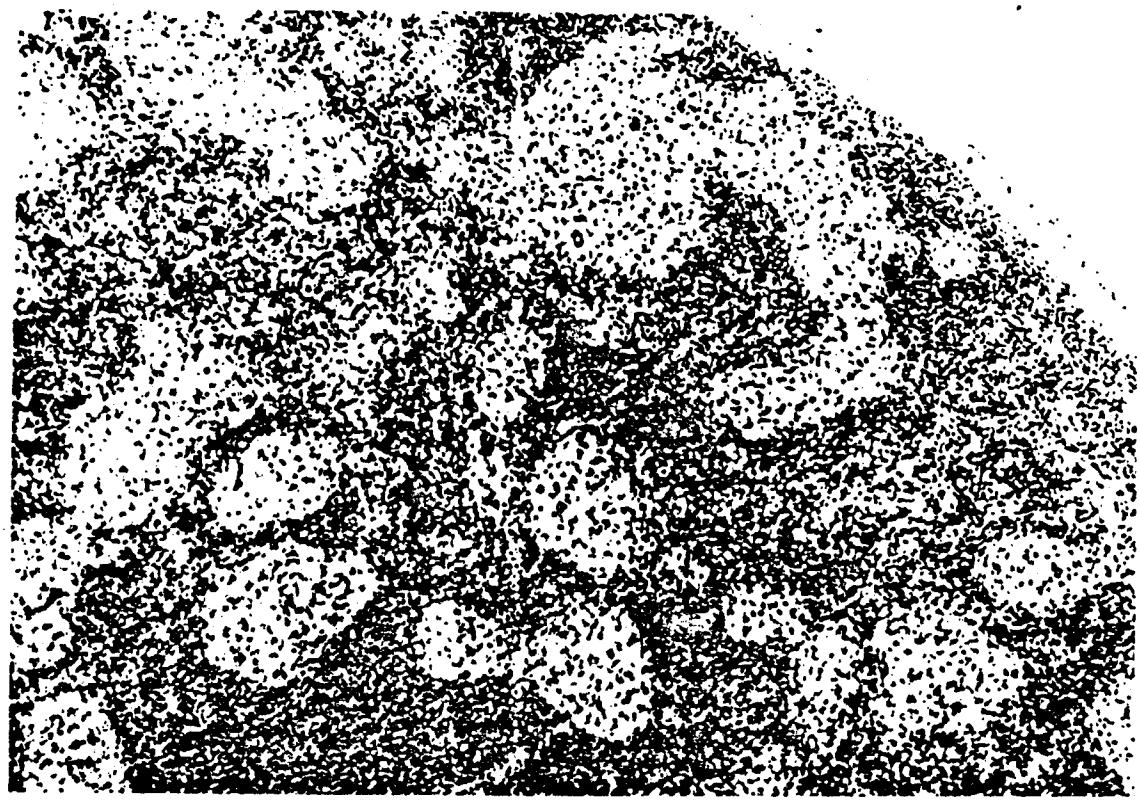

Figure 53. Thymic lymph node (25X), male rat, F04 group. Many small to large macrophage aggregates are present in the medullary area. The macrophages are laden with many fibrous glass particles.

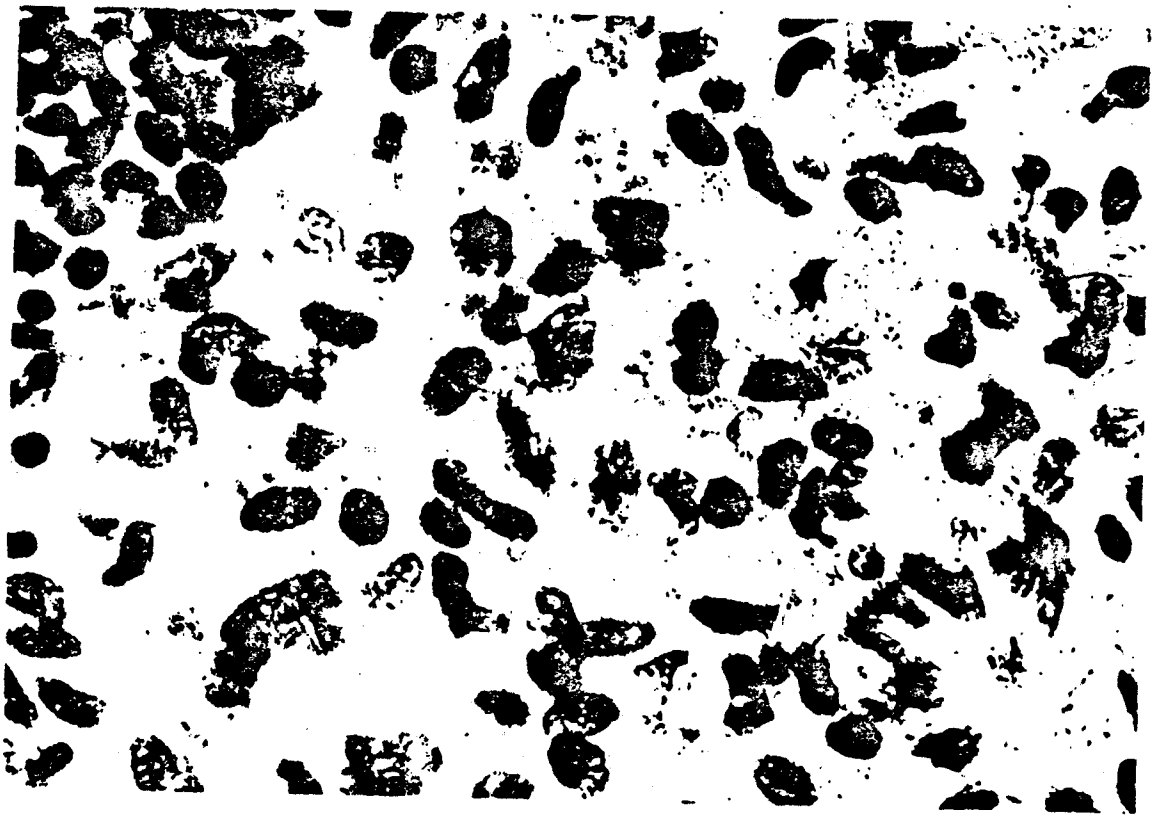

Figure 54. Thymic lymph node (250X - reduced light), male rat, F04 group. Fibrous glass particles are clearly depicted in this macrophage aggregate.

There were rather significant histomorphologic variations in qualitative and quantitative fibrous glass-related changes among the various exposure groups in the lungs and thymic and tracheobronchial lymph nodes. These changes were least pronounced in the F01 group, became progressively more pronounced in the F02 and F03 groups, and were most pronounced in the F04 group. In contrast to this, the gross changes seen in the lung lobes at the time of necropsy were most severe in the F02 group, were somewhat less severe in the F03 group, and were least severe in the F04 group, i.e., in relation to size of the plaque-like lesions of the pleura. The pleural lesions seen microscopically in many of the F04 group animals may have been relatively more significant (more lesions per unit area of pleura) than those seen in the F02 and F03 group animals because there were more lesions per unit area of pleura, i.e., the pleura was "granular" in character in many of the animals at necropsy. Hence a larger number of pleural lesions would be present per microscopic field resulting in a more "severe" lesion designation.

Table 47 depicts the numbers of animals affected per exposure group and qualitative severities of the fibrous glass-induced lesions in the lung and lymph nodes (thymic and tracheobronchial).

Many scheduled sacrifice rats in this study had mononuclear cell leukemia (Fischer rat leukemia) depicted in Table 48. Both the male and the female rats in the F05 (control) group had a lower incidence of mononuclear cell leukemia when compared to the male and female rats in the other test groups. When the males and females, early death and scheduled sacrifice, were considered together and a chi square analysis applied, the difference between the control group (F05) and each of the test groups was significant ($P < 0.05$) (Table 49).

Discussion

The response to fibrous glass inhalation was qualitatively similar in both rats and monkeys, in that the changes induced consisted of macrophage responses to the inhaled fibers. In both species there was translocation of fibers from the lung to draining lymph nodes and, with the exception of two rats in which fiber-laden macrophages were observed in mesenteric lymph nodes,

there was no further evidence of fiber translocation in rats or monkeys from this study. There was no evidence of fibrous glass-induced pulmonary carcinogenicity or carcinogenicity of serosal surfaces. The only question regarding carcinogenicity arose in the increase seen in the incidence of mononuclear cell leukemia in exposed vs. control rats (see discussion below). There was no evidence that the inhaled fibrous glass induced fibroplasia or any additional change other than the macrophage response in the lung or lymph nodes of either rats or monkeys. There was no evidence that the pleural adhesions observed at necropsy in one rat from the F01 group were associated with fibrous glass inhalation.

Fibrous glass-induced pulmonary lesions in monkeys were generally mild. With the exception of the F01 group (> 20 micrometer x 4 to 6 micrometer plus binder) in which the macrophage response was minimal and in which lymphoid aggregates increased mildly, there were no apparent differences in response among the fibrous glass-exposed groups. The significance of the increase in the lymphoid aggregates is unknown but the most probable explanation would be a mild stimulation from an antigen such as the binder. The response in rats increased in severity from Group F01 to Group F04 and consisted of foci of granulomatous inflammation that were not present in monkeys. It was more difficult to precisely define the response induced by the fibrous glass in monkeys because this response was generally superimposed on the lesions induced by lung mite infestations and the aggregates of macrophages often contained both lung mite debris and fibrous glass. Lung mite-induced pulmonary lesions were prominent in many monkeys from this study and were present to some degree in nearly all monkeys. Some of these lesions were similar to those that might be expected from inhaled fibers to include such changes as pleural, subpleural, and interstitial fibrosis as well as smooth muscle hyperplasia. The presence of parasite-induced lesions in the lungs of monkeys could have masked subtle changes induced by the fibrous glass. However, the nature and distribution of the fibrous glass-induced lesions and their consistency among all groups, including monkeys with minimal lung mite-associated lesions, suggests that this was not the case. There were no fibrous glass associated granulomas in monkeys as there were in rats.

The prescribed fiber diameter in Group F01 (4 to 6 micrometers) was of such dimension as to preclude most fibers from entering the alveoli. The presence of fibrous glass-induced lesions in this group in some animals from

both species, although minimal, probably occurred as a result of the presence of smaller diameter fibers that are inevitably present to some extent in these preparations.

Results from a previous fiberglass tracheal instillation and inhalation study in rats utilized fibers measuring either 1.5 micrometers x 5 micrometers or 1.5 micrometers x 60 micrometers[1]. The shorter fibers did not induce granulomas in the lung, instead fibers were phagocytized and cleared to the draining lymph nodes; however, the longer fibers induced granulomas and were not cleared to the lymph nodes[1]. The results in rats from the study herein described did not follow that pattern entirely as the most intense pulmonary response occurred in Group F04 where the fiber length was shortest. There was translocation of fibers to the regional lymph node even in the group with the longest fibers (F01, > 20 micrometers) indicating that either particles of this length can be phagocytized and cleared or that the phagocytized and transported fibers were fractured fibers of shorter length. As previously described, the response in monkeys was similar to that described for fibers of 1.5 micrometers x 5 micrometers in rats. However, the possibility for variation in response between species and the generally mild and consistent response in monkeys does not allow for viable comparisons with Gernstein et al.[34] in rats.

It was impossible to draw conclusions concerning the relative influence of fiber diameter, fiber length, concentration, or effect of binder on animals in this study because more than one variable was changed in each group and there were insufficient numbers of groups to isolate effects of any factor. Generally, the pulmonary response in rats was greater in groups with smaller diameter fibers as would be expected. That was true in monkeys only to the extent that the larger diameter fibers in the F01 group induced a less severe response than did fibers from the other three exposure groups.

The grossly visible plaque-like foci that occurred in rats resulted from accumulations of granulomatous foci in pleural and subpleural locations. The decreasing severity of these grossly observed lesions among three of the test groups (i.e., F02 > F03 > F04) was in direct contrast to the severity observed microscopically (i.e., F04 > F03 > F02). Although the explanation for this discrepancy was not entirely obvious, it apparently resulted from a

variation in character and in pleural localization of granulomatous foci that was not directly related to the general severity of the pulmonary lesions. These lesions were limited to granulomatous foci, there was no fibrosis, and there were no growth alterations in adjacent tissues, therefore there is no evidence in these animals that any further sequelae would result beyond that observed.

There was no consistent variation in occurrence and severity of fibrous glass-induced lesions among the various lobes of the lungs in monkeys. There was, however, a generally greater severity of such lesions in posterior lobes of the lungs in rats from Groups F02 and F03, whereas there was a more even distribution among all lobes in rats from Group F04. The extent to which fiber dimension influenced distribution could not be determined in this study.

The mononuclear cell leukemia was statistically significant when each test group was individually compared to the control group. This neoplasm is commonly seen in aged Fischer 344 rats. The incidence of mononuclear cell leukemia occurring in these control rats is essentially the same as that observed in control Fischer rats from 24-month studies over the past several years at Battelle's Columbus Laboratories. The reason for the increased incidence of mononuclear cell leukemia in test groups as compared to the control group in this study is not apparent. The possibility of an exposure-related increase in incidence of this neoplasm cannot be ruled out.

Conclusions

- The only unequivocal responses induced by fibrous glass inhalation in monkeys were macrophage aggregates with phagocytized fibrous glass in the lungs and tracheobronchial lymph nodes.
- The pulmonary responses in the rat induced by fibrous glass inhalation were characterized by macrophage aggregates and granulomas which contained fibrous glass fibers. The grossly visible plague like foci resulted from accumulations of granulomatous foci in pleural and subpleural locations. These lesions were limited to granulomatous foci, there was no fibrosis and there were no growth alterations in adjacent tissues, therefore there is no evidence in these animals that any further sequelae would result beyond that observed.

- There was no evidence of a fibrous glass induced fibrogenic response in either monkeys or rats.
- The most severe lesions in rats were in the F04 group (< 10 micrometers x 1 micrometer, no binder) whereas the response in the F01 group (>20 micrometers x 4 to 5 micrometers, with binder) was minimal.
- The severity of response in monkeys was similar for all exposed groups except the F01 group (>20 micrometers x 4 to 6 micrometers, with binder) in which the response was minimal. Group F01 also had monkeys which had mildly increased numbers of lymphoid nodules or aggregates in peribronchiolar and perivascular areas. The significance of the increase in the lymphoid aggregates is unknown but the most probable explanation would be a mild stimulation from an antigen such as the binder.
- The fibrous glass induced lesions were similarly distributed among all lobes of the lung in monkeys; in rats, the lesions were most prominent in posterior lobes in all but the F04 group where there was more equal distribution throughout the lung.
- The relative influence of fiber diameter, fiber length, concentration, and binder could not be evaluated due to variation of more than one factor in each animal group.
- The only evidence of translocation of fibers occurred in macrophage transport to draining pulmonary lymph nodes in many animals (rats and monkeys) and to mesenteric lymph nodes in two rats.
- The mononuclear cell leukemia was statistically significant when each test group was individually compared to the control group. The possibility of an exposure related incidence of this neoplasm cannot be ruled out.
- This study showed no evidence of pulmonary or mesothelial carcinogenicity associated with inhaled fibrous glass.

RESEARCH NEEDS

Presently, mechanistic studies are not available to explain the apparent effect of glass fiber inhalation on the incidence of mononuclear cell leukemia in Fisher 344 rats. Previous studies (Fisher and Wilson, J. Reticuloendoth. Soc., 27, 513, 1980; Wagner, J. Natl. Cancer Inst., 57, 509, 1976; Lee, et al., Environ. Res., 24, 167, 1981; and Sherwin, et al., Lab. Investig., 40, 576, 1979) have described effects of inhaled and instilled silicates on the immune response of laboratory animals and humans. Pulmonary macrophage aggregation and granuloma formation are observations common to many of the early studies and this study. It's reasonable to hypothesize that inhaled fibrous glass may have resulted in compromised immune function and an enhanced incidence of the spontaneously occurring mononuclear cell leukemia. This hypothesis is readily tested by evaluation of the immune response and tumor incidence and dissemination in Fischer 344 rats instilled with glass fibers and subsequently exposed in the transplanted tumor.
